The assumption that all unstable zeros of $\hat{U}$ are distinct can be removed and is included for ease of presentation. Note that the problem $\inf_{\Phi \in \ell_1} \{ \|\Phi\|_{\ell_1} : A\Phi = b \}$ appears to be infinite dimensional in $\Phi(t)$, $t = 0, 1, \dots$

The condition $A\Phi = b$ with $\Phi \in \ell_1$ replaces the constraint that $\Phi = H - U * Q$ with $Q \in \ell_1$. Here the “unstable” zeros of $\hat{U}$ are interpolated to obtain the condition $A\Phi = b$. Using the zero-interpolation, the seminal article (Dahleh and Pearson 1987) established that the optimal solution is a finite impulse response sequence where the dimension of the impulse response can be determined a priori. Suppose the dimension of the optimal impulse response Φ^o is N . Then the ℓ_1 optimal control problem in the SISO setting (with the assumption that $\hat{U}$ has no zeros on the unit circle) results in a finite dimensional problem that can be solved using linear programming. Indeed with A_N denoting a matrix which retains the first $N - 1$ columns of A the result below can be established.

Theorem 6 *The following holds:*

$$\begin{aligned} v = \inf_{\Phi \in R^N} \{ \|\Phi\|_{\ell_1} : A_N \Phi = b \} = & \min \sum_{k=0}^{N-1} (\Phi_+(k) + \Phi_-(k)) \\ & \text{subject to} \\ & A_N(\Phi_+(k) - \Phi_-(k)) = b \\ & \Phi_+(k) \geq 0, \Phi_-(k) \geq 0. \end{aligned}$$

The above strategy also proves effective in addressing other SISO problems where multiple objectives involving ℓ_1 and H_2 norm are present (see Salapaka et al. 1997 and Voulgaris 1995).

Though the design in the SISO case for ℓ_1 optimal controller can be obtained via a finite dimensional linear program, for the MIMO case, the strategy of casting the optimization problem in terms of the closed-loop map Φ alone by imposing zero-interpolation conditions does not suffice.

MIMO Case

For the MIMO case, consider translating the condition $\Phi = H - U * Q * V$, with $Q \in \ell_1$ to constraints only on Φ . Here, $\hat{U} \hat{Q} \hat{V} = \hat{H} - \hat{\Phi}$ where $\hat{U}$, $\hat{Q}$, $\hat{V}$ are $n_z \times n_u$, $n_u \times n_y$, $n_y \times n_w$ matrices of transfer functions where $\hat{H}$ and $\hat{\Phi}$ are $n_z \times n_w$ dimensional. There is no loss of generality in assuming that $\hat{U}$ and $\hat{V}$ have normal rank n_u and n_y , respectively. In the MIMO case, $\hat{U} \hat{Q} \hat{V} = \hat{H} - \hat{\Phi}$, with $Q \in \ell_1$, imposes conditions where the unstable zeros (now with directions) of $\hat{U}$ and $\hat{V}$ have to be interpolated by the zeros of $\hat{H} - \hat{\Phi}$. However, in the MIMO case, in addition to the zero-interpolation conditions, rank-interpolation conditions need to be imposed on $\hat{H} - \hat{\Phi}$ when $n_u = n_z$ and $n_y = n_w$ is not met. The rank-interpolation conditions impose infinite number of constraints on the impulse response Φ . Here one approach is to limit the number of rank interpolation constraints to a finite number and include only finite impulse response sequences for Φ that result in finite dimensional approximations to provide converging upper and lower bounds (see Dahleh and Diaz-Bobillo 1994). The limiting controller is obtained

by increasing the number of constraints and variables included, and the closed-loop map needs to guarantee that the corresponding $Q \in \ell_1$. In such an approach, there is little advantage in not including Q in the optimization.

Moreover, in a MIMO setting, it is more likely that a hard constraint is needed on the performance between an input-output pair while optimizing the ℓ_1 performance between another input-output pair. Thus consider the case where exogenous input, $w = \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}$ and the regulated output $z = \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}$.

For example suppose the model is uncertain with the uncertainty modeled by Δ , where it is known that $\|\Delta\|_{\ell_1} < \frac{1}{\gamma}$ and enters the system description as shown in Fig. 1b. Suppose the closed-loop map $\mathbf{F}_\ell(\mathbf{G}, \mathbf{K})$ is such that the closed-loop map from w_1 to z_1 has ℓ_1 norm less than γ . Then using small-gain theorem, it follows that the closed-loop system with Δ in Fig. 1b will remain stable. As stability is a primary concern, it is appropriate that the controller ensures that the ℓ_1 norm of the map from w_1 to z_1 be bounded by γ . Suppose in addition it is desired that ℓ_1 norm of the closed-loop transfer map Φ_{22} , from w_2 to z_2 , is small (a soft objective); see Fig. 2b. The resulting optimization problem takes the form:

$$\inf_{\mathbf{K} \text{ stabilizing}} \{ \|\Phi_{22}(\mathbf{K})\|_{\ell_1} : \|\Phi_{11}(\mathbf{K})\|_{\ell_1} \leq \gamma \}.$$

Using the Youla-Parametrization approach, closed-loop maps achieved via stabilizing controllers are given by $H - U * Q * V$ and the problem becomes

$$\nu = \inf_{Q \in \ell_1} \left\{ \|H^{22} - U^2 * Q * V^2\|_{\ell_1} : \right. \\ \left. \|H^{11} - U^1 * Q * V^1\|_{\ell_1} \leq \gamma \right\}.$$

The above problem might be ill-posed where there is no Q in ℓ_1 that achieves the infimizing value ν . This motivates including a “regularizing” constraint, on Q where the problem to be solved becomes

$$\nu = \inf_{Q \in \ell_1} \left\{ \|H^{22} - U^2 * Q * V^1\|_{\ell_1} : \|H^{11} - U^1 * Q * V^2\|_{\ell_1} \leq \gamma, \|Q\|_{\ell_1} \leq \beta \right\}. \quad (4)$$

The problem (4) is infinite dimensional in the impulse response parameters $Q(k)$. The following problems, where the closed-loop maps are truncated, provide a lower bound on ν for each N :

$$\nu_N = \inf_{Q \in \ell_1} \{ \|P_N(H^{22} - U^2 * Q * V^2)\|_{\ell_1} : \\ \|P_N(H^{11} - U^1 * Q * V^1)\|_{\ell_1} \leq \gamma, \\ \|Q\|_{\ell_1} \leq \beta \}. \quad (5)$$

Note that the above problem is finite-dimensional with $Q \in R^N$. The following problems provide upper bounds on ν by truncating the Youla parameter Q , for each N :

$$\nu^N = \inf_{Q \in \ell_1} \{ \|H^{22} - U^2 * P_N(Q) * V^2\|_{\ell_1} : \\ \|H^{11} - U^1 * P_N(Q) * V^1\|_{\ell_1} \leq \gamma, \\ \|P_N(Q)\|_{\ell_1} \leq \beta \}. \quad (6)$$

If it is assumed that $\hat{H}$, $\hat{U}$, and $\hat{V}$ have numerator polynomials with finite number of terms then it can be shown that (6) is a finite dimensional problem. The assumption that $\hat{H}$, $\hat{U}$, and $\hat{V}$ are polynomial matrices of λ is not restrictive; indeed, the denominator terms of $\hat{H}$, $\hat{U}$, and $\hat{V}$ which are stable can be absorbed into the parameter $\hat{Q}$.

Problems (5) and (6) associated with ν_N and ν^N can be solved via finite-dimensional linear programming following similar approach to the one presented for the SISO case in Theorem 6. Moreover, the following can be established.

Theorem 7 $\nu_N \nearrow \nu$ and $\nu^N \searrow \nu$.

The above methodology is elucidated in Qi et al. (2004) with accompanying software in Qi et al. (2001); here, it is also established that in the framework described above, it is relatively straightforward to incorporate structural constraints induced on the Q parameter that arise due to structural constraints on the controller $\mathbf{K}$. Another methodology is the scaled Q approach (Khammash 2000) where a scaled ℓ_1 norm of Q is introduced into the optimization objective which plays the role of the ℓ_1 norm constraint on the Q parameter in the regularized setup of (4).

Summary

The ℓ_1 optimal controller synthesis can incorporate time-domain constraints directly. For the SISO case, an optimal controller can be determined by solving a linear programming problem. For the MIMO case, under realistic assumptions, the optimal performance can be approximated within any desired accuracy by controllers determined via finite dimensional linear programming problems. Many of the mathematical tools employed for solving the ℓ_1 optimal controller problem have proven to be instrumental in solving larger class of problems including multi-objective controller synthesis problem (Elia and Dahleh 1997; Salapaka and Dahleh 2000). A key aspect of future efforts needs to be in adoption of the ℓ_1 control framework in applications.

Abstract

This chapter provides an overview of lane keeping systems (LKS). First, a general architecture is introduced common to both existing and future LKS, along with a description of the used sensors and actuators. Then, the threat

assessment and the lane position control problems are discussed highlighting challenges, existing solutions, and future directions.

Keywords

ADAS · Vehicle control · Intelligent transportation systems · Lane keeping

Introduction

Lane keeping systems aim at preventing unintended lane departures, which may lead to accidents involving surrounding obstacles and vehicles. This goal can be achieved by resorting to different combinations of sensor sets, threat assessment criteria, and interventions. For example, lane departure warning (LDW) systems monitor the lane markers through cameras installed behind the windshield and issue a (visual, acoustic, haptic) warning to the driver if the vehicle is too close to or has crossed the lane boundaries. The haptic warning typically consists of a slight counter-steering force or a vibration applied to the steering wheel. In Lane Departure Assist or Aid (LDA) systems, a steering torque is applied in order to keep the vehicle within the intended lane, once a crossing of the lane markings is detected or predicted within a certain time interval. Interventions and warnings can be differently combined, depending on the specific system implementation.

While basic LDW and LDA systems are triggered by crossing (or the prediction of crossing) the lane markers, more advanced (emergency) lane keeping systems (Cars 2019; Mercedes 2013) intervene if a threat of collision with the surrounding vehicles and objects is detected. Such advanced functionalities can be implemented by using radars to track the surrounding objects. Clearly, depending on the traffic scenario, assessing the threat of collision with surrounding vehicles may be complicated. Nevertheless, with the development (deployment) of autonomous driving (AD) technologies, enhanced perception and increased awareness of the surrounding traffic situation may allow interventions that also account for

the road users around the vehicle, thus allowing LDW/LDA systems to act only if necessary.

In this chapter, we overview the most important aspects in the design of a lane keeping system. The chapter is structured as follows. Section “Lane Keeping System Architecture” illustrates the architecture of a generic lane keeping system. Section “Sensing and Actuation” reviews the most used sensors suitable for lane keeping applications. Section “Decision-Making and Control” introduces the threat assessment and the lane position control problems highlighting the most relevant challenges.

Lane Keeping System Architecture

The main components of a LKS and their interconnections are shown in Fig. 1, where a general architecture is sketched that can describe existing LDW and LDA systems, as well as future LKS described in section “Introduction”.

Relative positions and velocities of the host vehicle are measured by one radar, typically installed on the front of the vehicle, and possibly by the camera, typically installed behind the windshield. Position of the host vehicle within the lane and further information like road geometry are measured by the camera. These measurements are then fused by the *sensor fusion* module to provide accurate measurements of the position and velocity of the vehicle w.r.t. the surrounding environment and the lane in

the widest range of operating conditions and scenarios.

The task of the *decision-making and control module* is to assess the risk that the vehicle crosses the lane in a dangerous way and, possibly, to take an action that can range from warning the driver or issuing an assisting intervention like braking and/or steering. Such steering and braking commands are actually implemented by *low-level controllers*.

The different modules will be overviewed in the following sections.

Sensing and Actuation

Current LKS systems rely on a sensor package consisting of a forward-looking radar and camera, which are described next in sections “Radar” and “Vision Systems”. Additional sensors, in some system already available (Cars 2017), may include rear-looking radars and cameras and blind spot cameras, which are installed in the side mirrors.

Radar

Radars for automotive applications are placed in the front of the car, typically behind the grille. The radar emits radio millimeter waves, and distance from the vehicle ahead is calculated by measuring the arrival time and direction of the reflected radio waves. The relative velocity is determined by relying on the Doppler effect, i.e., by measuring the frequency change of the

Lane Keeping Systems, Fig. 1 The lane keeping architecture

reflected waves. Relative distance and velocity measurements are typically updated with a frequency of 10–15 Hz.

Radars for automotive applications emit waves within a frequency range of 24–77 GHz and detect objects within an approximate range of 150 m and a view angle of about $\pm 10^\circ$, with a deviation of 20–30 cm from the correct value for 95% of the measurements (Eidehall 2004). New radar systems support the *multimode* operation, increasing the range up to about 200 m with a view angle of about $\pm 10^\circ$ (News Releases Denso Corporation 2013a). In particular, *multimode* radars can switch between two modes, namely, one with shorter range and wider view angle and the other with longer range and narrower view angle.

Typically, radar units are equipped with computer systems running signal processing algorithms that detect and track objects and, for each of them, calculate relative position and speed and azimuth angle and also provide additional information like the time an object has been tracked and a flag indicating that a target has been locked. Such additional information are typically used in implementing the decision-making algorithms of, among others, the lane keeping system.

There are several issues arising from the use of a radar in automotive applications like wave reflections due to road bumps or barriers that may induce the signal processing algorithms to false object detections (Eidehall 2004). Moreover, interference and the vehicle dynamics (News Releases Denso Corporation 2013a) like pitching due to braking may limit the capability of the signal processing algorithms of correctly detecting and tracking the surrounding objects. The latter may be solved by, e.g., using electric motors that adjust the radar antenna axes in order to compensate for the vehicle dynamics (News Releases Denso Corporation 2013a).

Vision Systems

Vision systems in lane keeping applications are typically based on a single, CCD camera mounted next to the rear view mirror placed at the center of the windshield. The image

is typically captured by 640 times 480 pixels and then processed by an image processing unit. The sampling time of the vision system is about 0.1 s, but it can change depending on, e.g., the complexity of the scene, for example, in city traffic (Eidehall 2004). For instance, sampling times lower than 0.1 s are used in LKA applications.

Lane markings are detected by using differences in the image contrast (Technology Daimler and Safety Innovation 2013). The camera can be either monochrome or full color. The latter is used to enhance the detection of lane markings, which have different colors around the world (News Releases Denso Corporation 2013b). Distances to the lane markings and road geometry parameters like heading angle and curvature are determined by the image processing algorithms, which must be robust to bad weather conditions or worn lane markings. Estimation of road geometry parameters like curvature measurement can be a challenging problem (Lundquist and Schön 2011), especially with rain or fog (Eidehall 2004).

Depending on the image processing algorithms the cameras are equipped with, surrounding objects can also be detected and tracked. In particular, pattern recognition algorithm can be used to find objects in the images and classify them into cars, trucks, motorcycles, and pedestrians. Vehicles (or other objects) can be typically detected in a range of about 60–70 m, with lower accuracy than a radar (Eidehall 2004).

Actuators

In order to keep the vehicle within its lane, the most convenient actuator is the steering. Hence, a lane keeping system can be quite easily built in those vehicles equipped with Electric Power Assist Steering (EPAS) systems. In particular, an additional steering torque can be added by the EPAS to the driver's steering torque, in order to generate the desired yaw moment calculated by the *decision-making and control module*.

Clearly, the steering command is not the only one available that affects the vehicle yaw motion, thus changing its orientation and lateral position within the lane. Individual wheel braking

may also be used (Technology Daimler and Safety Innovation 2013). In particular, in vehicles equipped with yaw motion control system via individual braking, a braking torque request for each wheel can be sent to the yaw motion control system in order to generate the desired yaw moment.

Decision-Making and Control

The decision-making and control in a lane keeping problem can be conceptually divided into two tasks: *the threat assessment* and *the lane position control*. The threat assessment problem can be stated as the problem of detecting the risk of accident due to an unintended lane departure for a given situation of the surrounding environment (i.e., surrounding vehicles and obstacles). The lane position control problem is the problem of controlling the vehicle yaw and lateral motion in order to stay within the lane. The lane position control is activated once the threat assessment detects the risk of accident.

We point out that the border between the corresponding modules executing these two tasks may be blur for different existing commercial lane keeping systems, i.e., the two problems cannot be solved by two separate modules, but rather can be seen and solved as a single problem. Moreover, the following presentation of the threat assessment and the lane position control problems and approaches abstracts from the implementation of a particular lane keeping system available on the market, rather than focusing on fundamental concepts.

As a last remark, it should be noticed that *override functionalities* are always present in LKSs, to immediately return the control of the vehicle to the driver. Typically, the driver's steering commands resulting in large steering torques are not counteracted by the system, which rather lets the driver gain the control of the vehicle.

Threat Assessment

The core information in a threat assessment algorithm for lane keeping applications is given by a measure called Time to Lane Crossing (TLC).

This is the predicted time when a front tire intersects a lane boundary. As explained in van Winsum et al. (2000), the TLC can be calculated in different ways. Next, its simplest expression is reported (Eidehall 2004):

$$\text{TLC} = \frac{W/2 - W_{\text{veh}}/2 - y_{\text{off}}}{\dot{y}_{\text{off}}} \quad (1)$$

where W is the lane width, y_{off} is the vehicle lateral position within the lane, and W_{veh} is the vehicle width. Equation (1) can be easily modified to calculate the TLC w.r.t. any lane boundary relative to the adjacent lanes.

The simplest way of using the TLC is just monitoring it and triggering an action as the TLC passes a threshold. Nevertheless, depending on the vehicle manufacturer, more sophisticated algorithms can be developed in order to correctly interpret the driver's intention and minimize unnecessary assisting interventions. Next, a few scenarios follow that must be taken into account while developing such algorithms in order not to interfere with the driver. In particular, the threat assessment module should stop or not trigger any assisting intervention while the vehicle is approaching or crossing a lane boundary if

- the indicators are active;
- a risk of collision with the preceding vehicle is detected, such that the vehicle is crossing the lane markings as results of an evasive maneuver;
- the radar detects a slower vehicle ahead and the driver accelerates, since this may be an overtaking (Technology Daimler and Safety Innovation 2013);
- the driver's steering wheel torque indicates that the driver is acting against the system;
- the driver manually initiates a maneuver driving the vehicle back to its lane (i.e., the driver executes "the correct" maneuver);
- the vehicle enters a motorway or a bend (Technology Daimler and Safety Innovation 2013).

Part of the threat assessment task is predicting the trajectories of the surrounding vehicles. For instance, if a *threat* vehicle is traveling in the

adjacent lane (in the same or opposite direction), its position has to be predicted at the TLC in order to decide whether to trigger an intervention, if a collision is predicted, or not (Eidehall 2004). This step is repeated for all the detected threat vehicles, provided that the onboard radar and the camera support multiple target tracking.

In order to minimize the interference of the lane keeping system with the driver and/or to not let the system perform dangerous maneuvers, assisting interventions should not be triggered if the quality of the measurements is such that the information about the surrounding environment is poor. For instance, in case of low visibility that limits the detection of the lane markings and the estimation of the road geometry, the system should be temporarily deactivated or downgraded.

In summary, the threat assessment module has to be designed with the objective of detecting the risk of accident due to lane departure while not interfering with the driver with unnecessary interventions (i.e., nuisance minimization).

Lane Position Control

As observed in section “Actuators”, the vehicle motion within the lane can be affected in two ways, i.e., through steering and individual wheel braking. Clearly, a steering command can be issued by both the driver and the lane keeping system.

Before issuing a steering command, in order to minimize the system nuisance, the lane keeping system can issue other types of low-intrusiveness interventions. For instance, if a “low”-level threat is detected by the threat assessment module (i.e., a threat where the risk of accidents is not imminent), warnings or other stimuli to the driver can be issued in order to induce the driver to execute the right maneuver. For instance, based on, e.g., spectrum analysis of the driver’s steering command, driver’s inattention or drowsiness may be detected and a warning issued. As observed in Technology Daimler and Safety Innovation (2013), different types of warning can be used for different vehicle types ranging from a vibration motor in the steering wheel to a sound or a vibrating seat for passenger vehicles. In trucks,

audible, directional warning signals can be used to let the driver know that the vehicle trajectory needs to be adjusted. In buses, in order to avoid bothering the passengers, driver warning is issued through vibration motors placed in the driver’s seat.

Other types of “soft intervention” aim at increasing the steering impedance in the direction leading to lane crossing that might cause a collision with surrounding vehicles. Generating the desired steering impedance can be easily formulated as a steering torque control problem. Nevertheless, tuning the control algorithm to obtain the desired steering feeling can be an involving and time-consuming procedure based on extensive in-vehicle testing.

Besides warnings and “soft interventions” aiming at inducing the driver to perform correct maneuvers, as part of the lane position control task in a lane keeping system, a lateral control algorithm w.r.t. the lane boundaries is needed. Consider the vehicle sketched in Fig. 2. The equations describing the vehicle motion within the lane can be compactly written in a state-space form as follows:

$$\dot{x} = Ax + B\delta + D\dot{\psi}_{\text{des}} \quad (2)$$

where $x = [e_y \ \dot{e}_y \ e_\psi \ \dot{e}_\psi]$ is the vector of lateral position and yaw errors and error rates, respectively; $\dot{\psi}_{\text{des}}$ is the desired yaw rate, e.g., calculated based on the road curvature; and A , B , and D are speed-dependent matrices that can be found in Rajamani (2006). The (unstable) system can be stabilized by a state feedback control law:

$$\delta = -Kx + \delta_{\text{ff}} \quad (3)$$

where K is a stabilizing static gain and δ_{ff} is a feedforward term that can be used to compensate for the road curvature. In Rajamani (2006), it is shown that, while $e_y(t) \rightarrow 0$ as $t \rightarrow \infty$, e_ψ approaches a nonzero steady-state value, no matter how δ_{ff} is chosen, for non-straight road.

Despite a simple problem formulation and solution, controlling the vehicle position within the lane is not a trivial task. Indeed, having the

Lane Keeping Systems, Fig. 2 Vehicle modeling notation

control law (3) active all time may increase the nuisance leading to unacceptable driving experience. For this reason, the steering command calculated through Eq.(3) may be active only when the vehicle significantly deviates from the road centerline, i.e., approaches the lane markings. Clearly, adding such conditions complicates the analysis of the closed-loop behavior, thus making necessary extensive in-vehicle tuning and verification.

Abstract

This chapter presents a brief introduction to learning control of quantum systems. Gradient-based learning methods, evolutionary computation algorithms, and reinforcement learning approaches are outlined for searching optimal or robust fields in quantum control problems. The state-of-the-art methods and future directions in learning control of quantum systems are discussed.

Keywords

Quantum control · Quantum learning
control · Quantum optimal control ·
Quantum robust control · Quantum systems

Introduction

Controlling quantum systems has become a central task in the development of quantum technologies, and quantum control has witnessed rapid progress in the last two decades; for an overview, see, e.g., the survey papers (Dong and Petersen 2010; Rabitz et al. 2000; Glaser et al. 2015; Brif et al. 2010; Altafini and Ticozzi 2012) or the monographs (Wiseman and Milburn 2010; D'Alessandro 2007). The general goal of

quantum control is to actively manipulate and control the dynamics of quantum systems for achieving given objectives (Acín et al. 2018; Guo et al. 2019) (e.g., rapid state transfer, high-fidelity gate operation). Two of fundamental issues in quantum control include investigating controllability of quantum systems and designing control laws to achieve expected control systems performance. Controllability is concerned with what control targets can be achieved and the controllability of finite-dimensional closed systems has been well addressed (D'Alessandro 2007). A few results on the controllability of open quantum systems have also been presented. For control law design, optimal control theory (Dong and Petersen 2010), Lyapunov control approaches (Kuang et al. 2017), learning control algorithms (Rabitz et al. 2000), and robust control methods (Dong et al. 2020) have been developed in manipulating quantum systems for achieving various control objectives.

Among various control design approaches, learning control is recognized as a powerful method for many complex quantum control tasks and has achieved great success in laser control of molecules and other applications since the approach was presented in the seminal paper (Judson and Rabitz 1992). Many quantum control tasks may be formulated as an optimization problem, and a learning algorithm can be employed to search for an optimal control field satisfying a desired performance condition. Gradient algorithms have been demonstrated to be an excellent candidate for numerically finding an optimal field and have achieved successful applications in nuclear magnetic resonance (NMR) systems due to their high efficiency (Khaneja et al. 2005). In many other optimal control problems, the gradient information may not be easy to obtain, and some complex problems may have local optima. For these situations, stochastic search algorithms usually have improved performance to find a good control field. The genetic algorithm (GA) and differential evolution (DE) (Dong et al. 2020) have been widely used in the area of quantum control of molecular systems and achieved great success (Rabitz et al. 2000). Another task

in quantum control is to achieve robustness performance in quantum systems. Gradient-based learning algorithms and stochastic search algorithms may be smartly modified to search for robust control fields. Also, some other machine learning algorithms such as reinforcement learning have found successful applications in various tasks (e.g., quantum error correction Fösel et al. 2018).

Gradient-Based Learning for Optimal Control of Quantum Systems

Consider a finite-dimensional quantum control system where its state $|\psi(t)\rangle$ (using the Dirac notation) is described by the following Schrödinger equation (setting $\hbar = 1$):

$$\begin{aligned} \frac{d}{dt}|\psi(t)\rangle &= -i[H_0 + \sum_{m=1}^M u_m(t)H_m]|\psi(t)\rangle, \quad t \in [0, T], \end{aligned} \quad (1)$$

where H_0 is the free Hamiltonian of the system and $H_c(t) = \sum_{m=1}^M u_m(t)H_m$ is the control Hamiltonian at time t that represents the interaction of the system with the external fields $u_m(t)$. The H_m are Hermitian operators through which the controls couple to the system. The objective of quantum optimal control is to find control fields $u_m(t)$ for maximizing a performance functional Φ . Φ may be a given functional of the state $|\psi\rangle$ and control defined according to practical requirement. For example, the fidelity $\Phi = |\langle\psi(T)|\psi_f\rangle|^2$ between the final state $|\psi(T)\rangle$ and target state $|\psi_f\rangle$ or the expectation $\Phi = |\langle\psi(T)|\hat{O}|\psi(T)\rangle|^2$ of an operator $\hat{O}$ may be defined as a performance index for state transfer task. In order to maximize the performance Φ , we may employ the GRAPE (gradient ascent pulse engineering) algorithm (Khaneja et al. 2005) or the Krotov method (Jäger et al. 2014) to search for the control field. For simplicity, we may discretize time T in N equal steps and during each step let the control fields u_m be

constant. The basic idea in the GRAPE algorithm is that the control fields are iteratively updated following the gradient direction of $\frac{\delta\Phi}{\delta u_m(k)}$ with a learning rate η , i.e.,

$$u_m(k+1) = u_m(k) + \eta \frac{\delta\Phi}{\delta u_m(k)}. \quad (2)$$

The gradient-based learning method can also be extended to the optimal control problem of unitary transformations (e.g., quantum gates) and open quantum systems. For example, for a unitary transformation U , its evolution is described by the following equation:

$$\dot{U}(t) = -i[H_0 + \sum_{m=1}^M u_m(t)H_m]U(t), \quad U(0) = I. \quad (3)$$

Now the objective is to design the controls $u_m(t)$ to steer the unitary $U(t)$ from $U(0) = I$ to a desired target U_F with high fidelity. We may define the performance function as $\Phi = |\langle U_F | e^{i\varphi} U(T) \rangle|^2$ for an arbitrary phase factor φ . Then we can calculate the gradient $\delta\Phi/\delta u_m(k)$, and the optimal control field can be searched for by following the gradient (Dong et al. 2016). When we consider the optimal control problem of an open quantum system, its state should be represented by a density matrix ρ and its dynamics should be described by a master equation. The dynamics of a Markovian open quantum system can be described using the following master equation in the Lindblad form as (Wiseman and Milburn 2010)

$$\begin{aligned} \dot{\rho}(t) &= -i[H_0 + \sum_{m=1}^M u_m(t)H_m, \rho(t)] \\ &+ \sum_k \gamma_k \mathcal{D}[L_k]\rho(t), \end{aligned} \quad (4)$$

where the non-negative coefficients γ_k specify the relevant relaxation rates, L_k are appropriate Lindblad operators, and $\mathcal{D}[L_k]\rho = (L_k\rho L_k^\dagger - \frac{1}{2}L_k^\dagger L_k\rho - \frac{1}{2}\rho L_k^\dagger L_k)$. The open GRAPE algorithm has also been developed to calculate the gradient based on the master equation (see Schulte-Herbrüggen et al. 2011).

Using the basic idea of gradient-based learning control, some variants have been developed for various requirements in quantum optimal control. For example, a data-driven gradient optimization algorithm (d-GRAPE) has been proposed to correct deterministic gate errors in high-precision quantum control by jointly learning from a design model and the experimental data from quantum tomography (Wu et al. 2018). A gradient-based frequency-domain optimization algorithm has been developed to solve the optimal control problem with constraints in the frequency domain (Shu et al. 2016). Existing results show that gradient-based learning methods can usually achieve excellent performance for solving optimal control problems when the system model is known and the dynamics can be equivalently (or approximately) described using a closed quantum system. This is also analyzed using quantum control landscape theory (Chakrabarti and Rabitz 2007).

Evolutionary Computation for Learning Control of Quantum Systems

Gradient algorithms have shown powerful capability for numerically finding optimal controls due to their excellent performance (Khaneja et al. 2005). In many practical applications, it may be difficult to obtain the gradient information or there exist local optima in complex quantum control problems. For these situations, a natural idea is to employ stochastic search algorithms to seek good controls. Evolutionary computation including GA and DE has been widely used in the area of quantum control. In these evolutionary computation methods, crossover, mutation, and selection operations are iteratively implemented to search for good solutions (optimal controls) in a parameter space. For example, a subspace-selective self-adaptive differential evolution (SUSSADE) algorithm has been proposed to achieve a high-fidelity single-shot Toffoli gate and single-shot three-qubit gates (Zahedinejad et al. 2015, 2016). Existing results showed that

DE with equally mixed strategies can achieve improved performance for quantum control problems (Ma et al. 2017). Several promising evolution algorithms have been investigated comparatively in Zahedinejad et al. (2014), and it was found that DE usually outperformed GA and particle swarm optimization for hard quantum control problems.

The above introduction of gradient-based learning and evolutionary computation mainly involves open-loop control strategies. Evolutionary computation has demonstrated extremely powerful capability when it is integrated into closed-loop control design. Closed-loop learning control, where each cycle of the closed loop is executed on a new sample, has achieved great successes in the laser control of laboratory chemical reactions (Rabitz et al. 2000; Judson and Rabitz 1992). A closed-loop learning control procedure generally involves three components (Dong and Petersen 2010; Rabitz et al. 2000): (i) a trial laser control input, (ii) the laboratory generation of the control that is applied to the sample and subsequently observed for its impact, and (iii) a learning algorithm to suggest the form of the next control input by considering the prior experiments. The initial trial control input may be a random input field or a well-designed laser pulse. A feature of a good closed-loop learning control design is its insensitivity to the initial trials. A key task is to develop a good learning algorithm for ensuring that the learning process converges to achieve a predetermined objective. GA, DE, and several rapid convergence algorithms have been developed for this task (Brif et al. 2010; Judson and Rabitz 1992). The optimal control problem is usually formulated as solving an optimization problem by maximizing a functional which is related to some variables such as the control inputs, quantum states, and control time but may have no analytical form. In the learning process, the optimization problem is solved iteratively. First, a trial input is applied to a sample to be controlled and the result is observed. Second, a learning algorithm suggests a better control input based on the prior experiments. Third, the “better” control input is applied to a new sample. This process continues until the

control objective is achieved or the maximum permitted iteration number is reached. It is often feasible to produce many identical-state samples for laboratory chemical molecules. If the control objective is well selected, there is a capability to apply specified control inputs to the samples, and the learning algorithm is sufficiently smart for searching for good control inputs, this process will converge and an optimal control pulse can be found (Rabitz et al. 2000).

Learning-Based Quantum Robust Control

The robust control of quantum systems has been recognized as a key task in developing practical quantum technology since the existence of noise and uncertainties is unavoidable. Learning control is an effective candidate for achieving robust performance in some quantum control problems (Dong et al. 2020). We first consider the control problem of inhomogeneous quantum ensembles. An inhomogeneous quantum ensemble consists of many individual quantum systems (e.g., atoms, molecules, or spin systems), and the parameters describing the system dynamics of these individual systems could have variations (Li and Khaneja 2006; Chen et al. 2014a). An example is that a spin ensemble in NMR may encounter large dispersion in the strength of the applied radio-frequency field and there also exist variations in the natural frequencies of these spins (Li and Khaneja 2006). Inhomogeneous quantum ensembles have wide applications in many fields ranging from quantum memory to magnetic resonance imaging. Hence, it is highly desirable to design control laws for an inhomogeneous ensemble to employ the same control inputs to steer individual systems with different dynamics from a given initial state to a target state.

A sampling-based learning control (SLC) method has been developed to achieve high-fidelity control of inhomogeneous quantum ensembles (Chen et al. 2014a). Consider an inhomogeneous ensemble in which the Hamiltonian of each individual system has the following form:

$$H_{\omega,\theta}(t) = \omega H_0 + \sum_{m=1}^M \theta u_m(t) H_m. \quad (5)$$

We assume that the parameters $\omega \in [1 - \Omega, 1 + \Omega]$ and $\theta \in [1 - \Theta, 1 + \Theta]$ and the constants $\Omega \in [0, 1]$ and $\Theta \in [0, 1]$ represent the bounds of the parameter dispersion. The objective is to design the controls $\{u_m(t)\}$ to simultaneously stabilize the individual systems (with different ω and θ) of the quantum ensemble from an initial state $|\psi_0\rangle$ to the same target state $|\psi_f\rangle$ with high fidelity. This task can be achieved using the SLC method including two steps of “training” and “testing and evaluation” (Chen et al. 2014a). In the training step, we select N samples from the quantum ensemble regarding the distribution (e.g., uniform distribution) of the inhomogeneity parameters and then construct a generalized system as follows:

$$\begin{aligned} \frac{d}{dt} \begin{pmatrix} |\psi_{\omega_1, \theta_1}(t)\rangle \\ |\psi_{\omega_2, \theta_2}(t)\rangle \\ \vdots \\ |\psi_{\omega_N, \theta_N}(t)\rangle \end{pmatrix} \\ = -i \begin{pmatrix} H_{\omega_1, \theta_1}(t) |\psi_{\omega_1, \theta_1}(t)\rangle \\ H_{\omega_2, \theta_2}(t) |\psi_{\omega_2, \theta_2}(t)\rangle \\ \vdots \\ H_{\omega_N, \theta_N}(t) |\psi_{\omega_N, \theta_N}(t)\rangle \end{pmatrix} \end{aligned} \quad (6)$$

where $H_{\omega_n, \theta_n} = \omega_n H_0 + \sum_m \theta_n u_m(t) H_m$ with $n = 1, 2, \dots, N$. The cost function for the generalized system is defined by

$$\Phi_N(u) := \frac{1}{N} \sum_{n=1}^N \Phi_{\omega_n, \theta_n}(u). \quad (7)$$

The task of the training step is to find a control strategy u^* to maximize the cost functional $\Phi_N(u)$. A gradient-based learning algorithm (s-GRAPE) can be developed to complete this task. In the process of testing and evaluation, a number of sampling individual systems are randomly selected to evaluate the control performance. Results show that the SLC method is potential for control design of various inhomogeneous

quantum ensembles (including inhomogeneous open quantum ensembles).

Besides inhomogeneous quantum ensembles, the SLC method is useful for robust control of single quantum systems with various uncertainties. For example, Eq. (5) can also correspond to the Hamiltonian of a quantum system with inaccurate model parameter ω and uncertain multiplicative noise θ . In order to achieve robust control for such a quantum system, we may employ the SLC method to search for robust control pulses (Dong et al. 2015a, b; Wu et al. 2017). The performance of SLC approach can be further improved by exploring the richness and diversity of samples. Inspired by deep learning, a batch-based gradient algorithm (b-GRAPE) has been presented for efficiently seeking robust quantum controls, and numerical results showed that b-GRAPE can achieve improved performance over the SLC method for remarkably enhancing the control robustness while maintaining high fidelity (Wu et al. 2019). In other applications where we need to enhance the robustness in closed-loop learning control, we may either use the Hessian matrix information (Xing et al. 2014) or integrate the idea of SLC into the learning algorithm in searching for robust control fields. For example, an improved DE algorithm (called as *msMS_DE*) has been proposed to search for robust femtosecond laser pulses to control fragmentation of the molecule CH_2BrI (Dong et al. 2020). In *msMS_DE*, multiple samples are used for fitness evaluation and a mixed strategy is employed for the mutation operation.

Reinforcement Learning for Quantum Control

Reinforcement learning (RL) (Sutton and Barto 1998) is another important machine learning approach, and it addresses the problem of how an active agent can learn to approximate an optimal strategy while interacting with its environment. It is a model-free feedback-based approach and works well even when the system model is unknown or with uncertainties. RL has been used for learning control of quantum systems.

For example, a fidelity-based probabilistic Q-learning approach has been presented to naturally solve the balance problem between exploration and exploitation and was applied to learning control of quantum systems (Chen et al. 2014b). The authors in Bukov et al. (2018) showed that the performance of RL is comparable to optimal control approaches in the task of finding a short and high-fidelity protocol, controlling from an initial to a given target state in nonintegrable many-body quantum systems of interacting qubits. RL can also help identify variational protocols with nearly optimal fidelity even in the glassy phase. In Niu et al. (2019), deep reinforcement learning is employed to simultaneously optimize the speed and fidelity of quantum computation against both leakage and stochastic control errors. A universal quantum control framework was presented to improve the control robustness by adding control noise into training environments for RL agents trained with trusted region policy optimization. By utilizing two-stage learning with teacher and student networks and a reward quantifying the capability to recover the quantum information stored in a quantum system, the authors in Fösel et al. (2018) showed how a network-based “agent” in RL can discover good quantum error correction strategies to protect qubits against noise.

Conclusions

Machine learning has shown powerful capability in discovering high-quality controls to achieve optimal control and enhance robust performance for quantum systems. This chapter briefly introduces typical applications of machine learning to quantum control and illustrates how learning algorithms can assist in solving control problems of quantum systems with improved performance.

Summary and Future Directions

Learning control has been one of the main control design methods for quantum systems. Gradient-based methods have shown their efficiency advantages in numerically solving

quantum optimal and robust control problems. Evolutionary learning approaches including genetic algorithms and differential evolution algorithms have potential for control of open quantum systems and laboratory quantum control design. Reinforcement learning may provide an effective method for solving quantum control problems with feedback.

Future directions of quantum learning control include the following: (1) to further develop or improve existing machine learning algorithms to effectively solve complex (especially high-dimensional) quantum control problems emerged from new quantum technologies; (2) to explore various cutting-edge machine learning techniques (e.g., deep learning) for applications in the area of quantum control; (3) to integrate machine learning algorithms into quantum control experimental design for saving expensive quantum resources (i.e., quantum entanglement and quantum coherence) and discovering quantum mechanism; and (4) to develop novel quantum machine learning algorithms for simulating complex quantum control systems.

Abstract

In a Nash equilibrium, each player selects a strategy that is optimal with respect to the strategies of other players. This definition does not mention the process by which players

reach a Nash equilibrium. The topic of learning in games seeks to address this issue in that it explores how simplistic learning/adaptation rules can lead to Nash equilibrium. This entry presents a selective sampling of learning rules and their long-run convergence properties, i.e., conditions under which player strategies converge or not to Nash equilibrium.

Keywords

Cournot best response · Fictitious play · Log-linear learning · Mixed strategies · Nash equilibrium

Introduction

In a *Nash equilibrium*, each player's strategy is optimal with respect to the strategies of other players. Accordingly, Nash equilibrium offers a predictive model of the outcome of a game. That is, given the basic elements of a game – (i) a set of players; (ii) for each player, a set of strategies; and (iii) for each player, a utility function that captures preferences over strategies – one can model/assert that the strategies selected by the players constitute a Nash equilibrium.

In making this assertion, there is no suggestion of *how* players may come to reach a Nash equilibrium. Two motivating quotations in this regard are:

The attainment of equilibrium requires a disequilibrium process (Arrow 1986).

and

The explanatory significance of the equilibrium concept depends on the underlying dynamics (Skyrms 1992).

These quotations reflect that a foundation for Nash equilibrium as a predictive model is dynamics that lead to equilibrium. Motivated by these considerations, the topic of “learning in games” shifts the attention away from equilibrium and towards underlying dynamic processes and their long-run behavior. The intent is to understand how players may reach an equilibrium as well

as understand possible barriers to reaching Nash equilibrium.

In the setup of learning in games, players repetitively play a game over a sequence of stages. At each stage, players use past experiences/observations to select a strategy for the current stage. Once player strategies are selected, the game is played, information is updated, and the process is repeated. The question is then to understand the long-run behavior, e.g., whether or not player strategies converge to Nash equilibrium.

Traditionally the dynamic processes considered under learning in games have players selecting strategies based on a myopic desire to optimize for the current stage. That is, players do not consider long-run effects in updating their strategies. Accordingly, while players are engaged in repetitive play, the dynamic processes generally are not optimal in the long run (as in the setting of “repeated games”). Indeed, the survey article of Hart (2005) refers to the dynamic processes of learning in games as “adaptive heuristics.” This distinction is important in that an implicit concern in learning in games is to understand how “low rationality” (i.e., suboptimal and heuristic) processes can lead to the “high rationality” (i.e., mutually optimal) notion of Nash equilibrium.

This entry presents a sampling of results from the learning in games literature through a selection of illustrative dynamic processes, a review of their long-run behaviors relevant to Nash equilibrium, and pointers to further work.

Illustration: Commuting Game

We begin with a description of learning in games in the specific setting of the commuting game, which is a special case of so-called congestion games (cf., Roughgarden 2005). The setup is as follows. Each player seeks to plan a path from an origin to a destination. The origins and destinations can differ from player to player. Players seek to minimize their own travel times. These travel times depend both on the chosen path (distance traveled) and the paths of other players (road congestion). Every day, a player uses past

information and observations to select that day’s path according to some selection rule, and this process is repeated day after day.

In game-theoretic terms, player “strategies” are paths linking their origins to destinations, and player “utility functions” reflect travel times. At a Nash equilibrium, players have selected paths such that no individual player can find a shorter travel time given the chosen paths of others. The learning in games question is then whether player paths indeed converge to Nash equilibrium in the long run. Not surprisingly, the answer depends on the specific process that players use to select paths and possible additional structure of the commuting game.

Suppose that one of the players, say “Alice,” is choosing among a collection of paths. For the sake of illustration, let us give Alice the following capabilities: (i) Alice can observe the paths chosen by all other players and (ii) Alice can compute off-line her travel time as a function of her path and the paths of others.

With these capabilities, Alice can compute running averages of the travel times along all available paths. Note that the assumed capabilities allow Alice to compute the travel time of a path and hence its running average, *whether or not* she took the path on that day. With average travel time values in hand, two possible learning rules are:

- *Exploitation*: Choose the path with the lowest average travel time.
- *Exploitation with Exploration*: With high probability, choose the path with the lowest average travel time, and with low probability, choose a path at random.

Assuming that all players implement the same learning rule, each case induces a dynamic process that governs the daily selection of paths and determines the resulting long-run behavior. We will revisit these processes in a more formal setting in the next section.

A noteworthy feature of these learning rules is that they do not explicitly depend on the utility functions of other players. For example, suppose one of the other players is willing to trade off

travel time for more scenic routes. Similarly, suppose one of the other players prefers to travel on high congestion paths, e.g., a rolling billboard seeking to maximize exposure. The aforementioned learning rules for Alice remain unchanged. Of course, Alice's actions implicitly depend on the utility functions of other players, but only indirectly through their selected paths. This characteristic of no explicit dependence on the utility functions of others is known as “uncoupled” learning, and it can have major implications on the achievable long-run behavior (Hart and Mas-Colell 2003a).

In assuming the ability to observe the paths of other players and to compute off-line travel times as a function of these paths, these learning rules impose severe requirements on the information available to each player. Less restrictive are learning rules that are “payoff based” (Young 2005). A simple modification that leads to payoff-based learning is as follows. Alice maintains an empirical average of the travel times of a path using only the days that she took that path. Note the distinction – on any given day, Alice remains unaware of travel times for the routes not selected. Using these empirical average travel times, Alice can then mimic any of the aforementioned learning rules. As intended, she does not directly observe the paths of others, nor does she have a closed-form expression for travel times as a function of player paths. Rather, she only can select a path and measure the consequences. As before, all players implementing such a learning rule induce a dynamic process, but the ensuing analysis in payoff-based learning can be more subtle.

Learning Dynamics

We now give a more formal presentation of selected learning rules and results concerning their long-run behavior.

Preliminaries

We begin with the basic setup of games with a finite set of players, $\{1, 2, \dots, N\}$, and for each player i , a finite set of strategies, $\mathcal{A}_i$. Let

$$\mathcal{A} = \mathcal{A}_1 \times \dots \times \mathcal{A}_N$$

denote the set of strategy profiles. Each player, i , is endowed with a utility function

$$u_i : \mathcal{A} \rightarrow \mathbb{R}.$$

Utility functions capture player preferences over strategy profiles. Accordingly, for any $a, a' \in \mathcal{A}$, the condition

$$u_i(a) > u_i(a')$$

indicates that player i prefers the strategy profile a over a' .

The notation $-i$ indicates the set of players *other than* player i . Accordingly, we sometimes write $a \in \mathcal{A}$ as (a_i, a_{-i}) to isolate a_i , the strategy of player i , versus a_{-i} , the strategies of other players. The notation $-i$ is used in other settings as well.

Utility functions induce best-response sets. For $a_{-i} \in \mathcal{A}_{-i}$, define

$$\mathcal{B}_i(a_{-i}) = \{a_i : u_i(a_i, a_{-i}) \geq u_i(a'_i, a_{-i}) \text{ for all } a'_i \in \mathcal{A}_i\}.$$

In words, $\mathcal{B}_i(a_{-i})$ denotes the set of strategies that are optimal for player i in response to the strategies of other players, a_{-i} .

A strategy profile $a^* \in \mathcal{A}$ is a *Nash equilibrium* if for any player i and any $a'_i \in \mathcal{A}_i$,

$$u_i(a_i^*, a_{-i}^*) \geq u_i(a'_i, a_{-i}^*).$$

In words, at a Nash equilibrium, no player can achieve greater utility by unilaterally changing strategies. Stated in terms of best-response sets, a strategy profile, a^* , is a Nash equilibrium if for every player i ,

$$a_i^* \in \mathcal{B}_i(a_{-i}^*).$$

We also will need the notions of *mixed strategies* and mixed strategy Nash equilibrium. Let $\Delta(\mathcal{A}_i)$ denote probability distributions (i.e., non-negative vectors that sum to one) over the set

$\mathcal{A}_i$. A mixed strategy profile is a collection of probability distributions, $\alpha = (\alpha_1, \dots, \alpha_N)$, with $\alpha_i \in \Delta(\mathcal{A}_i)$ for each i . Let us assume that players choose a strategy randomly and independently according to these mixed strategies. Accordingly, define $\mathbf{Pr}[a; \alpha]$ to be the probability of strategy a under the mixed strategy profile α , and define the expected utility of player i as

$$U_i(\alpha) = \sum_{a \in \mathcal{A}} u_i(a) \cdot \mathbf{Pr}[a; \alpha].$$

A *mixed strategy Nash equilibrium* is a mixed strategy profile, α^* , such that for any player i and any $\alpha'_i \in \Delta(\mathcal{A}_i)$,

$$U_i(\alpha_i^*, \alpha_{-i}^*) \geq U_i(\alpha'_i, \alpha_{-i}^*).$$

Special Classes of Games

We will reference three special classes of games: (i) zero-sum games, (ii) potential games, and (iii) weakly acyclic games.

Zero-sum games: There are only two players (i.e., $N = 2$), and $u_1(a) = -u_2(a)$.

Potential games: There exists a (potential) function,

$$\phi : \mathcal{A} \rightarrow \mathbb{R}$$

such that for any pair of strategies, $a = (a_i, a_{-i})$ and $a' = (a'_i, a_{-i})$, that differ only in the strategy of player i ,

$$u_i(a_i, a_{-i}) - u_i(a'_i, a_{-i}) = \phi(a_i, a_{-i}) - \phi(a'_i, a_{-i}).$$

Weakly acyclic games: There exists a function

$$\phi : \mathcal{A} \rightarrow \mathbb{R}$$

with the following property: if $a \in \mathcal{A}$ is *not* a Nash equilibrium, then at least one player, say player i , has an alternative strategy, say $a'_i \in \mathcal{A}_i$, such that

$$u_i(a'_i, a_{-i}) > u_i(a_i, a_{-i})$$

and

$$\phi(a'_i, a_{-i}) > \phi(a_i, a_{-i}).$$

Potential games are a special class of games for which various learning dynamics converge to a Nash equilibrium. The aforementioned commuting game constitutes a potential game under certain special assumptions. These are as follows: (i) the delay on a road only depends on the number of users (and not their identities) and (ii) all players measure delay in the same manner (Monderer and Shapley 1996).

Weakly acyclic games are a generalization of potential games. In potential games, there exists a potential function that captures differences in utility under unilateral (i.e., single player) changes in strategy. In weakly acyclic games (see Young 1998), if a strategy profile is not a Nash equilibrium, then there *exists* a player who can simultaneously achieve an increase in utility while increasing the potential function. The characterization of weakly acyclic games through a potential function herein is not traditional and is borrowed from Marden et al. (2009a).

Forecasted Best-Response Dynamics

One family of learning dynamics involves players formulating a forecast of the strategies of other players based on past observations and then playing a best response to this forecast.

Cournot Best-Response Dynamics

The simplest illustration is Cournot best-response dynamics. Players repetitively play the same game over stages $t = 0, 1, 2, \dots$. At stage t , a player forecasts that the strategies of other players are the strategies played at the previous stage $t - 1$. The following rules specify Cournot best response with inertia. For each stage t and for each player i :

- With probability $p \in (0, 1)$, $a_i(t) = a_i(t - 1)$ (inertia).
- With probability $1 - p$, $a_i(t) \in \mathcal{B}_i(a_{-i}(t - 1))$ (best response).
- If $a_i(t - 1) \in \mathcal{B}_i(a_{-i}(t - 1))$, then $a_i(t) = a_i(t - 1)$ (continuation).

Proposition 1 For weakly acyclic (and hence potential) games, player strategies under

Cournot best-response dynamics with inertia converge to a Nash equilibrium.

Cournot best-response dynamics need not always converge in games with a Nash equilibrium, hence the restriction to weakly acyclic games.

Fictitious Play

In fictitious play, introduced in Brown (1951), players also use past observations to construct a forecast of the strategies of other players. Unlike Cournot best-response dynamics, this forecast is *probabilistic*.

As a simple example, consider the commuting game with two players, Alice and Bob, who both must choose between two paths, *A* and *B*. Now suppose that on stage $t = 10$, Alice has observed Bob used path *A* for 6 out of the previous 10 days and path *B* for the remaining days. Then Alice's forecast of Bob is that he will chose path *A* with 60 % probability and path *B* with 40 % probability. Alice then chooses between path *A* and *B* in order to optimize her *expected* utility. Likewise, Bob uses Alice's empirical averages to form a probabilistic forecast of her next choice and selects a path to optimize his expected utility.

More generally, let $\pi_j(t) \in \Delta(\mathcal{A}_j)$ denote the *empirical frequency* for player j at stage t . This vector is a probability distribution that indicates the relative frequency of times player j played each strategy in $\mathcal{A}_j$ over stages $0, 1, \dots, t-1$. In fictitious play, player i assumes (incorrectly) that at stage t , other players will select their strategies independently and randomly according to their empirical frequency vectors. Let $\Pi_{-i}(t)$ denote the induced probability distribution over $\mathcal{A}_{-i}$ at stage t . Under fictitious play, player i selects an action according to

$$a_i(t) \in \arg \max_{a_i \in \mathcal{A}_i} \sum_{a_{-i} \in \mathcal{A}_{-i}} u_i(a_i, a_{-i}) \cdot \Pr[a_{-i}; \Pi_{-i}(t)].$$

In words, player i selects the action that maximizes expected utility assuming that other players select their strategies randomly and

independently according to their empirical frequencies.

Proposition 2 *For (i) zero-sum games, (ii) potential games, and (iii) two-player games in which one player has only two actions, player empirical frequencies under fictitious play converge to a mixed strategy Nash equilibrium.*

These results are reported in Fudenberg and Levine (1998), Hofbauer and Sandholm (2002), and Berger (2005). Fictitious play need not converge to Nash equilibria in all games. An early counterexample is reported in Shapley (1964), which constructs a two-player game with a unique mixed strategy Nash equilibrium. A weakly acyclic game with multiple pure (i.e., non-mixed) Nash equilibria under which fictitious play does not converge is reported in Foster and Young (1998).

A variant of fictitious play is “joint strategy” fictitious play (Marden et al. 2009b). In this framework, players construct as forecasts empirical frequencies of the *joint* play of other players. This formulation is in contrast to constructing and combining empirical frequencies for each player. In the commuting game, it turns out that joint strategy fictitious play is equivalent to the aforementioned “exploitation” rule of selecting the path with lowest average travel time. Marden et al. (2009b) show that action profiles under joint strategy fictitious play (with inertia) converge to a Nash equilibrium in potential games.

Log-Linear Learning

Under forecasted best-response dynamics, players chose a best response to the forecasted strategies of other players. Log-linear learning, introduced in Blume (1993), allows the possibility of “exploration,” in which players can select nonoptimal strategies but with relatively low probabilities.

Log-linear learning proceeds as follows. First, introduce a “temperature” parameter, $T > 0$.

- At stage t , a single player, say player i , is selected at random.
- For player i ,

$$\Pr[a_i(t) = a'_i] = \frac{1}{Z} e^{u_i(a'_i, a_{-i}(t-1))/T}.$$

- For all other players, $j \neq i$,

$$a_j(t) = a_j(t-1).$$

In words, under log-linear learning, only a single player performs a strategy update at each stage. The probability of selecting a strategy is exponentially proportional to the utility garnered from that strategy (with other players repeating their previous strategies). In the above description, the dummy parameter Z is a normalizing variable used to define a probability distribution. In fact, the specific probability distribution for strategy selection is a Gibbs distribution with temperature parameter, T . For very large T , strategies are chosen approximately uniformly at random. However, for small T , the selected strategy is a best response (i.e., $a_i(t) \in \mathcal{B}_i(a_{-i}(t-1))$) with high probability, and an alternative strategy is selected with low probability.

Because of the inherent randomness, strategy profiles under log-linear learning never converge. Nonetheless, the long-run behavior can be characterized probabilistically as follows.

Proposition 3 *For potential games with potential function $\phi(\cdot)$ under log-linear learning, for any $a \in \mathcal{A}$,*

$$\lim_{t \rightarrow \infty} \Pr[a(t) = a] = \frac{1}{Z} e^{\phi(a)/T}.$$

In words, the long-run probabilities of strategy profiles conform to a Gibbs distribution constructed from the underlying potential function. This characterization has the important implication of (probabilistic) equilibrium *selection*. Prior convergence results stated convergence to Nash equilibria, but did not specify which Nash equilibrium in the case of multiple equilibria. Under log-linear learning, there is a probabilistic preference for the Nash equilibrium that maximizes the underlying potential function.

Extensions and Variations

Payoff-based learning. The discussion herein presumed that players can observe the actions of other players and can compute utility functions off-line. Payoff-based algorithms, i.e., algorithms in which players only measure the utility garnered in each stage, impose less restrictive informational requirements. See Young (2005) for a general discussion, as well as Marden et al. (2009c), Marden and Shamma (2012), and Arslan and Shamma (2004) for various payoff-based extensions.

No-regret learning. The broad class of so-called “no-regret” learning rules has the desirable property of converging to broader solution concepts (namely, Hannan consistency sets and correlated equilibria) in general games. See Hart and Mas-Colell (2000, 2001, 2003b) for an extensive discussion.

Calibrated forecasts. Calibrated forecasts are more sophisticated than empirical frequencies in that they satisfy certain long-run consistency properties. Accordingly, forecasted best-response learning using calibrated forecasts has stronger guaranteed convergence properties, such as convergence to correlated equilibria. See Foster and Vohra (1997), Kakade and Foster (2008), and Mannor et al. (2007).

Impossibility results. This entry focused on convergence results in various special cases. There are broad impossibility results that imply the impossibility of families of learning rules to converge to Nash equilibria in all games. The focus is on *uncoupled* learning, i.e., the learning dynamics for player i does not depend explicitly on the utility functions of other players (which is satisfied by all of the learning dynamics presented herein). See Hart and Mas-Colell (2003a, 2006), Hart and Mansour (2007), and Shamma and Arslan (2005). Another type of impossibility result concerns lower bounds on the required rate of convergence to equilibrium (e.g., Hart and Mansour 2010).

Welfare maximization. Of special interest is learning dynamics that select welfare (i.e., sum of utilities) maximizing strategy profiles, whether or not they are Nash equilibria. Recent contributions include Pradelski and Young (2012), Marden et al. (2011), and Arieli and Babichenko (2012).

Summary and Future Directions

We have presented a selection of learning dynamics and their long-run characteristics, specifically in terms of convergence to Nash equilibria. As stated early on, the original motivation of learning in games research has been to add credence to solution concepts such as Nash equilibrium as a model of the outcome of a game. An emerging line of research stems from engineering considerations, in which the objective is to use the framework of learning in games as a design tool for distributed decision architecture settings such as autonomous vehicle teams, communication networks, or smart grid energy systems. A related emerging direction is social influence, in which the objective is to steer the collective behaviors of human decision makers towards a socially desirable situation through the dispersment of incentives. Accordingly, learning in games can offer baseline models on how individuals update their behaviors to guide and inform social influence policies.

Learning Theory: The Probably Approximately Correct Framework

Mathukumalli Vidyasagar

University of Texas at Dallas, Richardson, TX, USA

Abstract

In this article, a brief overview is given of one particular approach to machine learning, known as PAC (probably approximately correct) learning theory. A central concept in PAC learning theory is the Vapnik-Chervonenkis (VC) dimension. Finiteness of the VC-dimension is sufficient for PAC learnability, and in some cases, is also necessary. Some directions for future research are also indicated.

Keywords

Machine learning · Probably approximately correct (PAC) learning · Support vector machine · Vapnik-Chervonenkis (V-C) dimension

Introduction

How does a machine learn an abstract concept from examples? How can a machine generalize to previously unseen situations? Learning theory

is the study of (formalized versions of) such questions. There are many possible ways to formulate such questions. Therefore, the focus of this entry is on one particular formalism, known as PAC (probably approximately correct) learning. It turns out that PAC learning theory is rich enough to capture intuitive notions of what learning should mean in the context of applications and, at the same time, is amenable to formal mathematical analysis. There are several precise and complete studies of PAC learning theory, many of which are cited in the bibliography. Therefore, this article is devoted to sketching some high-level ideas.

Problem Formulation

In the PAC formalism, the starting point is the premise that there is an unknown set, say an unknown convex polygon, or an unknown half-plane. The unknown set cannot be *completely* unknown; rather, something should be specified about its nature, in order for the problem to be both meaningful and tractable. For instance, in the first example above, the learner knows that the unknown set is a convex polygon, though it is not known *which* polygon it might be. Similarly, in the second example, the learner knows that the unknown set is a half-plane, though it is not known *which* half-plane. The collection of all possible unknown sets is known as the **concept class**, and the particular unknown set is referred to as the “target concept.” In the first example, this would be the set of all convex polygons and in the second case it would be the set of half-planes. The unknown set cannot be directly observed of course; otherwise, there would be nothing to learn. Rather, one is given clues about the target concept by an “oracle,” which informs the learner whether or not a particular element belongs to the target concept. Therefore, the information available to the learner is a collection of “labelled samples,” in the form $\{(x_i, I_T(x_i)), i = 1, \dots, m\}$, where m is the total number of labelled samples and $I_T(\cdot)$ is the indicator function of the target concept T . Based on this information, the learner is expected

to generate a “hypothesis” H_m that is a good approximation to the unknown target concept T .

One of the main features of PAC learning theory that distinguishes it from its forerunners is the observation that, no matter how many training samples are available to the learner, the hypothesis H_m can never *exactly equal* the unknown target concept T . Rather, all that one can expect is that H_m converges to T in some appropriate metric. Since the purpose of machine learning is to generate a hypothesis H_m that can be used to approximate the unknown target concept T for prediction purposes, a natural candidate for the metric that measures the disparity between H_m and T is the so-called generalization error, defined as follows: Suppose that, after m training samples that have led to the hypothesis H_m , a testing sample x is generated at random. One can now ask: what is the probability that the hypothesis H_m misclassifies x ? In other words, what is the value of $\Pr\{I_{H_m}(x) \neq I_T(x)\}$? This quantity is known as the generalization error, and the objective is to ensure that it approaches zero as $m \rightarrow \infty$.

The manner in which the samples are generated leads to different models of learning. For instance, if the learner is able to choose the next sample x_{m+1} on the basis of the previous m labelled samples, which is then passed on to the oracle for labeling, this is known as “active learning.” More common is “passive learning,” in which the sequence of training samples $\{x_i\}_{i \geq 1}$ is generated at random, in an independent and identically distributed (i.i.d.) fashion, according to some probability distribution P . In this case, even the hypothesis H_m and the generalization error are random, because they depend on the randomly generated training samples. This is the rationale behind the nomenclature “probably approximately correct.” The hypothesis H_m is not expected to equal to unknown target concept T exactly, only approximately. Even that is only probably true, because in principle it is possible that the randomly generated training samples could be totally unrepresentative and thus lead to a poor hypothesis. If we toss a coin many times, there is a small but always positive probability that it could turn up heads every time. As the coin

Learning Theory: The Probably Approximately Correct Framework,

Fig. 1 Examples of learning problems. (a) Learning half-planes. (b) Learning convex polygons

is tossed more and more times, this probability becomes smaller, but will never equal zero.

Examples

Example 1 Consider the situation where the concept class consists of all half-planes in $\mathbb{R}^2$, as indicated in the left side of Fig. 1. Here the unknown target concept T is some fixed but unknown half-plane. The symbol T is next to the boundary of the half-plane, and all points to the right of the line constitute the target half-plane. The training samples, generated at random according some unknown probability distribution P , are also shown in the figure. The samples that belong to T are shown as blue rectangles, while those that do not belong to T are shown as red dots. Knowing only these labelled samples, the learner is expected to guess what T might be.

A reasonable approach is to choose some half-plane that agrees with the data and correctly classifies the labelled data. For instance, the well-known support vector machine (SVM) algorithm chooses the unique half-plane such that the closest sample to the dividing line is as far as possible from it; see the paper by Cortes and Vapnik (1997).

The symbol H denotes the boundary of a hypothesis, which is another half-plane. The shaded region is the **symmetric difference** between the two half-planes. The set $T \Delta H$ is the set of points that are misclassified by the hypothesis H . Of course, we do not know what this set is, because we do not know T .

It can be shown that, whenever the hypothesis H is chosen to be **consistent** in the sense of correctly classifying all labelled samples, the generalization error goes to zero as the number of samples approaches infinity.

Example 2 Now suppose the concept class consists of all convex polygons in the unit square, and let T denote the (unknown) target convex polygon. This situation is depicted in the right side of Fig. 1. This time let us assume that the probability distribution that generates the samples is the uniform distribution on X . Given a set of positively and negatively labelled samples (the same convention as in Example 1), let us choose the hypothesis H to be the convex hull of all positively labelled samples, as shown in the figure. Since every positively labelled sample belongs to T , and T is a convex set, it follows that H is a subset of T . Moreover, $P(T \setminus H)$ is the generalization error. It can be shown that this algorithm also “works” in the sense that the generalization error goes to zero as the number of samples approaches infinity.

Vapnik-Chervonenkis Dimension

Given any concept class C , there is a single integer that offers a measure of the richness of the class, known as the Vapnik-Chervonenkis (or VC) dimension, after its originators.

Definition 1 A set $S \subseteq X$ is said to be **shattered** by a concept class C if, for every subset $B \subseteq S$, there is a set $A \in C$ such that $S \cap A = B$. The

Learning Theory: The Probably Approximately Correct Framework, Fig. 2 VC dimension illustrations. (a) Shattering a set of three elements. (b) Infinite VC dimension

VC dimension of C is the largest integer d such that there is a finite set of cardinality d that is shattered by C .

Example 3 It can be shown that the set of half-planes in $\mathbb{R}^2$ has VC dimension two. Choose a set $S = \{x, y, z\}$ consisting of three points that are not collinear, as in Fig. 2. Then there are $2^3 = 8$ subsets of S . The point is to show that for each of these eight subsets, there is a half-plane that contains precisely that subset, nothing more and nothing less. That this is possible is shown in Fig. 2. Four out of the eight situations are depicted in this figure, and the remaining four situations can be covered by taking the complement of the half-plane shown. It is also necessary to show that *no set with four or more elements can be shattered*, but that step is omitted; instead the reader is referred to any standard text such as Vidyasagar (1997). More generally, it can be shown that the set of half-planes in $\mathbb{R}^k$ has VC dimension $k + 1$.

Example 4 The set of convex polygons has infinite VC dimension. To see this, let S be a strictly convex set, as shown in Fig. 2b. (Recall that a set is “strictly convex” if none of its boundary points is a convex combination of other points in the set.) Choose any finite collection of boundary points, call it $S = \{x_1, \dots, x_n\}$. If B is a subset of S , then the convex hull of B does not contain any other point of S , due to the strict convexity property. Since this argument holds for every integer n , the class of convex polygons has infinite VC dimension.

Two Important Theorems

Out of the many important results in learning theory, two are noteworthy.

Theorem 1 (Blumer et al. (1989)) *A concept class is distribution-free PAC learnable if and only if it has finite VC dimension.*

Theorem 2 (Benedek and Itai (1991)) *Suppose P is a fixed probability distribution. Then the concept class C is PAC learnable if and only if, for every positive number ϵ , it is possible to cover C by a finite number of balls of radius ϵ , with respect to the pseudometric d_P .*

Now let us return to the two examples studied previously. Since the set of half-planes has finite VC dimension, it is distribution-free PAC learnable. The set of convex polygons can be shown to satisfy the conditions of Theorem 2 if P is the uniform distribution and is therefore PAC learnable. However, since it has infinite VC dimension, it follows from Theorem 1 that it is *not* distribution-free PAC learnable.

Summary and Future Directions

This brief entry presents only the most basic aspects of PAC learning theory. Many more results are known about PAC learning theory, and of course many interesting problems remain unsolved. Some of the known extensions are:

- Learning under an “intermediate” family of probability distributions $\mathcal{P}$ that is not neces-

sarily equal to $\mathcal{P}^*$, the set of *all* distributions (Kulkarni and Vidyasagar 1997)

- Relaxing the requirement that the algorithm should work uniformly well for all target concepts and requiring instead only that it should work with high probability (Campi and Vidyasagar 2001)
- Relaxing the requirement that the training samples are independent of each other and permitting them to have Markovian dependence (Gamarnik 2003; Meir 2000) or β -mixing dependence (Vidyasagar 2003)

There is considerable research in finding alternate sets of necessary and sufficient conditions for learnability. Unfortunately, many of these conditions are unverifiable and amount to tautological restatements of the problem under study.

Lie Algebraic Methods in Nonlinear Control

Matthias Kowski

School of Mathematical and Statistical Sciences,
Arizona State University, Tempe, AZ, USA

Abstract

Lie algebraic methods generalize matrix methods and algebraic rank conditions to smooth nonlinear systems. They capture the essence of noncommuting flows and give rise to noncommutative analogues of Taylor expansions. Lie algebraic rank conditions determine controllability, observability, and optimality. Lie algebraic methods are also employed for state-space realization, control design, and path planning.

Chen-Fliess series · Lie bracket

Definition

This article considers generally nonlinear control systems (affine in the control) of the form

This work was partially supported by the National Science Foundation through the grant DMS 09-08204.

$$\begin{aligned}\dot{x} &= f_0(x) + u_1 f_1(x) + \dots + u_m f_m(x) \\ y &= \varphi(x)\end{aligned}\quad (1)$$

where the state x takes values in $\mathbb{R}^n$, or more generally in an n -dimensional manifold M^n , the f_i are smooth vector fields, $\varphi: \mathbb{R}^n \mapsto \mathbb{R}^p$ is a smooth output function, and the controls $u = (u_1, \dots, u_m): [0, T] \mapsto U$ are piecewise continuous, or, more generally, measurable functions taking values in a closed convex subset $U \subseteq \mathbb{R}^m$ that contains 0 in its interior.

Lie algebraic techniques refers to analyzing the system (1) and designing controls and stabilizing feedback laws by employing relations satisfied by iterated Lie brackets of the system vector fields f_i .

Introduction

Systems of the form (1) contain as a special case time-invariant linear systems $\dot{x} = Ax + Bu$, $y = Cx$ (with constant matrices $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, and $C \in \mathbb{R}^{p \times n}$) that are well-studied and are a mainstay of classical control engineering. Properties such as controllability, stabilizability, observability, and optimal control and various others are determined by relationships satisfied by higher-order matrix products of A , B , and C .

Since the early 1970s, it has been well understood that the appropriate generalization of this matrix algebra, and, e.g., invariant linear subspaces, to nonlinear systems is in terms of the Lie algebra generated by the vector fields f_i , integral submanifolds of this Lie algebra, and the algebra of iterated Lie derivatives of the output function.

The Lie bracket of two smooth vector fields $f, g: M \mapsto TM$ is defined as the vector field $[f, g]: M \mapsto TM$ that maps any smooth function $\varphi \in C^\infty(M)$ to the function $[f, g]\varphi = fg\varphi - gf\varphi$.

In local coordinates, if

$$f(x) = \sum_{i=1}^n f^i(x) \frac{\partial}{\partial x^i} \quad \text{and}$$

$$g(x) = \sum_{i=1}^n g^i(x) \frac{\partial}{\partial x^i},$$

then

$$\begin{aligned}[f, g](x) &= \sum_{i,j=1}^n \left(f^j(x) \frac{\partial g^i}{\partial x^j}(x) \right. \\ &\quad \left. - g^j(x) \frac{\partial f^i}{\partial x^j}(x) \right) \frac{\partial}{\partial x^i}.\end{aligned}$$

With some abuse of notation, one may abbreviate this to $[f, g] = (Dg)f - (Df)g$, where f and g are considered as column vector fields and Df and Dg denote their Jacobian matrices of partial derivatives.

Note that with this convention the Lie bracket corresponds to the negative of the commutator of matrices: If $P, Q \in \mathbb{R}^{n \times n}$ define, in matrix notation, the linear vector fields $f(x) = Px$ and $g(x) = Qx$, then $[f, g](x) = (QP - PQ)x = -[P, Q]x$.

Noncommuting Flows

Geometrically the Lie bracket of two smooth vector fields f_1 and f_2 is an infinitesimal measure of the lack of commutativity of their flows. For a smooth vector field f and an initial point $x(0) = p \in M$, denote by $e^{tf}p$ the solution of the differential equation $\dot{x} = f(x)$ at time t . Then

$$\begin{aligned}[f_1, f_2]\varphi(p) &= \lim_{t \rightarrow 0} \frac{1}{2t^2} \left(\varphi \left(e^{-tf_2} e^{-tf_1} e^{tf_2} e^{tf_1} p \right) \right. \\ &\quad \left. - \varphi(p) \right).\end{aligned}$$

As a most simple example, consider parallel parking a unicycle, moving it sideways without slipping. Introduce coordinates (x, y, θ) for the location in the plane and the steering angle. The dynamics are governed by $\dot{x} = u_1 \cos \theta$, $\dot{y} = u_1 \sin \theta$, and $\dot{\theta} = u_2$ where the control u_1 is interpreted as the signed rolling speed and u_2 as the angular velocity of the steering angle. Written in the form (1), one has $f_1 = (\cos \theta, \sin \theta, 0)^T$ and $f_2 = (0, 0, 1)^T$. (In this

case the drift vector field $f_0 \equiv 0$ vanishes.) If the system starts at $(0, 0, 0)^T$, then via the sequence of control actions of the form *turn left*, *roll forward*, *turn back*, and *roll backwards*, one may steer the system to a point $(0, \Delta y, 0)^T$ with $\Delta y > 0$. This sideways motion corresponds to the value $(0, 1, 0)^T$ of the Lie bracket $[f_1, f_2] = (-\sin \theta, \cos \theta, 0)^T$ at the origin. It encapsulates that steering and rolling do not commute. This example is easily expanded to model, e.g., the sideways motion of a car, or a truck with multiple trailers; see, e.g., Bloch (2003), Bressan and Piccoli (2007), and Bullo and Lewis (2005). In such cases longer iterated Lie brackets correspond to the required more intricate control actions needed to obtain, e.g., a pure sideways motion.

In the case of linear systems, if the Kalman rank condition $\text{rank}[B, AB, A^2B, \dots, A^{n-1}B] = n$ is not satisfied, then all solutions curves of the system starting from the same point $x(0) = p$ are at all times $T > 0$ constrained to lie in a proper affine subspace. In the nonlinear setting the role of the compound matrix of that condition is taken by the Lie algebra $L = L(f_0, f_1, \dots, f_m)$ of all finite linear combinations of iterated Lie brackets of the vector fields f_i . As an immediate consequence of the Frobenius integrability theorem, if at a point $x(0) = p$ the vector fields in L span the whole tangent space, then it is possible to reach an open neighborhood of the initial point by concatenating flows of the system (1) that correspond to piecewise constant controls. Conversely, in the case of analytic vector fields and a compact set U of admissible control values, the Hermann-Nagano theorem guarantees that if the dimension of the subspace $L(p) = \{f(p) : f \in L\} < n$ is not maximal, then all such trajectories are confined to stay in a lower-dimensional proper integral submanifold of L through the point p . For a comprehensive introduction, see, e.g., the textbooks Bressan and Piccoli (2007), Isidori (1995), and Sontag (1998).

Controllability

Define the reachable set $\mathcal{R}_T(p)$ as the set of all terminal points $x(T; u, p)$ at time T

of trajectories of (1) that start at the initial point $x(0) = p$ and correspond to admissible controls. Commonly known as the *Lie algebra rank condition* (LARC), the above condition determines whether the system is accessible from the point p , which means that for arbitrarily small time $T > 0$, the reachable set $\mathcal{R}_T(p)$ has nonempty n -dimensional interior. For most applications one desires stronger controllability properties. Most amenable to Lie algebraic methods, and practically relevant, is small-time local controllability (STLC): The system is STLC from p if p lies in the interior of $\mathcal{R}_T(p)$ for every $T > 0$. In the case that there is no drift vector field f_0 , accessibility is equivalent to STLC. However, in general, the situation is much more intricate, and a rich literature is devoted to various necessary or sufficient conditions for STLC. A popular such condition is the Hermes condition. For this define the subspaces $S^1 = \text{span}\{(\text{ad}^j f_0, f_i) : 1 \leq j \leq m, i \in \mathbb{Z}^+\}$, and recursively $S^{k+1} = \text{span}\{[g_1, g_k] : g_1 \in S^1, g_k \in S^k\}$. Here $(\text{ad}^0 f, g) = g$, and recursively $(\text{ad}^{k+1} f, g) = [f, (\text{ad}^k f, g)]$. The Hermes condition guarantees in the case of analytic vector fields and, e.g., $U = [-1, 1]^m$ that if the system satisfies the (LARC) and for every $k \geq 1$, $S^{2k}(p) \subseteq S^{2k-1}(p)$, then the system is (STLC). For more general conditions, see Sussmann (1987) and also Kawski (1990) for a broader discussion.

The importance and value of Lie algebraic conditions may in large part be ascribed to their geometric character, their being invariant under coordinate changes and feedback. In particular, in the analytic case, the Lie relations completely determine the local properties of the system, in the sense that Lie algebra homomorphism between two systems gives rise to a local diffeomorphism that maps trajectories to trajectories (Sussmann 1974).

Exponential Lie Series

A central analytic tool in Lie algebraic methods that takes the role of Taylor expansions in classical analysis of dynamical system is the Chen-Fliess series which associates to every admissible

control $u: [0, T] \mapsto U$ a formal power series

$$\text{CF}(u, T) = \sum_I \int_0^T du^I \cdot X_{i_1} \dots X_{i_s} \quad (2)$$

over a set $\{X_0, X_1, \dots, X_m\}$ of noncommuting indeterminates (or *letters*). For every multi-index $I = (i_1, i_2, \dots, i_s) \in \{0, 1, \dots, m\}^s$, $s \geq 0$, the coefficient of X_I is the iterated integral defined recursively

$$\int_0^T du^{(I, j)} = \int_0^T \left(\int_0^t u^I \right) du_j(t). \quad (3)$$

Upon evaluating this series via the substitutions $X_i \longleftarrow f_i$, it becomes an *asymptotic series for the propagation of solutions of (1)*: For f_j, φ analytic, U compact, p in a compact set, and $T \geq 0$ sufficiently small, one has

$$\varphi(x(t; u, p)) = \sum_I \int_0^T du^I \cdot (f_{i_1} \dots f_{i_s} \varphi)(p). \quad (4)$$

One application of particular interest is to construct approximating systems of a given system (1) that preserve critical geometric properties, but which have a simpler structure. One such class is that of nilpotent systems, that is, systems whose Lie algebra $L = L(f_0, f_1, \dots, f_m)$ is nilpotent, and for which solutions can be found by simple quadratures. While truncations of the Chen-Fliess series never correspond to control systems of the same form, much work has been done in recent years to rewrite this series in more useful formats. For example, the infinite directed exponential product expansion in Sussmann (1986) that uses Hall trees immediately may be interpreted in terms of free nilpotent systems and consequently helps in the construction of nilpotent approximating systems. More recent work, much of it of a combinatorial algebra nature and utilizing the underlying Hopf algebras, further simplifies similar expansions and in particular yields explicit formulas for a continuous Baker-Campbell-Hausdorff formula or for the logarithm of the Chen-Fliess series (Gehrig and Kawski 2008).

Observability and Realization

In the setting of linear systems a well-defined algebraic sense dual to the concept of controllability is that of observability. Roughly speaking the system (1) is observable if knowledge of the output $y(t) = \varphi(x(t; u, p))$ over an arbitrarily small interval suffices to construct the current state $x(t; u, p)$ and indeed the past trajectory $x(\cdot; u, p)$. In the linear setting observability is equivalent to the rank condition $\text{rank}[C^T, (CA)^T, \dots, (CA^{n-1})^T] = n$ being satisfied. In the nonlinear setting, the place of the rows of this compound matrix is taken by the functions in the observation algebra, which consists of all finite linear combinations of iterated Lie derivatives $f_{i_s} \dots f_{i_1} \varphi$ of the output function.

Similar to the Hankel matrices introduced in the latter setting, in the case of a finite Lie rank, one again can use the output algebra to construct realizations in the form of (1) for systems which are initially only given in terms of input-output descriptions, or in terms of formal Fliess operators; see, e.g., Fliess (1980), Gray and Wang (2002), and Jakubczyk (1986) for further reading.

Optimal Control

In a well-defined geometric way, conditions for optimal control are dual to conditions for controllability and thus are directly amenable to Lie algebraic methods. Instead of considering a separate functional

$$J(u) = \psi(x(T; u, p)) + \int_0^T L(t, x(t; u, p), u(t)) dt \quad (5)$$

to be minimized, it is convenient for our purposes to augment the state by, e.g., defining $\dot{x}_0 = 1$ and $\dot{x}_{n+1} = L(x_0, x, u)$. For example, in the case of time-optimal control, one again obtains an enlarged system of the same form (1); else one utilizes more general Lie algebraic methods that also apply to systems not necessarily affine in the control.

The basic picture for systems with a compact set U of admissible values of the controls involves the attainable funnel $\mathcal{R}_{\leq T}(p)$ consisting of all trajectories of the system (1) starting at $x(0) = p$ that correspond to admissible controls. The trajectory corresponding to an optimal control u^* must at time T lie on the boundary of the funnel $\mathcal{R}_{\leq T}(p)$ and hence also at all prior times (using the invariance of domain property implied by the continuity of the flow). Hence one may associate a covector field along such optimal trajectory that at every time points in the direction of an outward normal. The Pontryagin Maximum Principle is a first-order characterization of such trajectory covector field pairs. Its pointwise maximization condition essentially says that if at any time $t_0 \in [0, T]$ one replaces the optimal control $u^*(\cdot)$ by any admissible control variation on an interval $[t_0, t_0 + \varepsilon]$, then such variation may be transported along the flow to yield, in the limit as $\varepsilon \searrow 0$, an *inward* pointing tangent vector to the reachable set $\mathcal{R}_T(p)$ at $x(T; u^*, p)$. To obtain stronger higher-order conditions for maximality, one may combine several such families of control variations. The effects of such combinations are again calculated in terms of iterated Lie brackets of the vector fields f_i . Indeed, necessary conditions for optimality, for a trajectory to lie on the boundary of the funnel $\mathcal{R}_{\leq T}(p)$, immediately translate into sufficient conditions for STLC, for the initial point to lie in the interior of $\mathcal{R}_T(p)$, and vice versa. For recent work employing Lie algebraic methods in optimality conditions, see, e.g., Agrachev et al. (2002).

Summary and Future Research

Lie algebraic techniques may be seen as a direct generalization of matrix linear algebra tools that have proved so successful in the analysis and design of linear systems. However, in the nonlinear case, the known algebraic rank conditions still exhibit gaps between necessary and sufficient conditions for controllability and optimality. Also, new, not yet fully understood, topological and resonance obstructions stand in the way of

controllability implying stabilizability. Systems that exhibit special structure, such as living on Lie groups, or being second order such as typical mechanical systems, are amenable to further refinements of the theory; compare, e.g., the use of affine connections and the symmetric product in Bullo et al. (2000). Other directions of ongoing and future research involve the extension of Lie algebraic methods to infinite dimensional systems and to generalize formulas to systems with less regularity; see, e.g., the work by Rampazzo and Sussmann (2007) on Lipschitz vector fields, thereby establishing closer connections with nonsmooth analysis (Clarke 1983) in control.

Linear Matrix Inequality Techniques in Optimal Control

Robert E. Skelton
Texas A&M University, College Station, TX,
USA

Abstract

LMI (linear matrix inequality) techniques offer more flexibility in the design of dynamic linear systems than techniques that minimize a scalar functional for optimization. For linear state space models, multiple goals (performance bounds) can be characterized

in terms of LMIs, and these can serve as the basis for controller optimization via finite-dimensional convex feasibility problems. LMI formulations of various standard control problems are described in this entry, including dynamic feedback stabilization, covariance control, LQR, H_∞ control, and L_∞ control. The integration of control and information architecture design (i.e., adding sensor/actuator precision selection to the control problem) is also shown to be a convex problem by formulating the feasibility constraints as LMIs.

Keywords

Control system design · Covariance control · H_∞ control · L_∞ control · LQR/LQG · Matrix inequalities · Sensor/actuator design · Integrated plant and control design

Early Optimization History

Hamilton invented state space models of nonlinear dynamic systems with his generalized momenta work in the 1800s (Hamilton 1834, 1835), but at that time the lack of computational tools prevented broad acceptance of the first-order form of dynamic equations. With the rapid development of computers in the 1960s, state space models evoked a formal control theory for minimizing a scalar function of control and state, propelled by the calculus of variations and Pontryagin's maximum principle. Optimal control has been a pillar of control theory for the last 50 years. In fact, all of the problems discussed in this entry might be solvable by minimizing a scalar functional, but an unsolved search is required to find the right functional (e.g., finding weights in an LQG formulation). Globally convergent algorithms are available to do just that for quadratic functionals, where an iterative algorithm with proven convergence can find the weights, and each iteration requires solving new Riccati equations. However, more direct methods are now available to do this just using LMIs.

Since the 1990s, a major focus for linear system design has been to pose control problems as feasibility problems, to satisfy multiple constraints. Since then, feasibility approaches have dominated design decisions, and such feasibility problems may be convex or non-convex. If the constraint problem can be reduced to a set of linear matrix inequalities (LMIs), then convexity is proven. However, failure to find such LMI formulations of the problem does not prove the problem is not convex. Computer-assisted methods for convex problems are available to avoid the search for LMIs (see Camino et al. 2003a).

In the case of linear dynamic models of stochastic processes, optimization methods led to the popularization of linear quadratic Gaussian (LQG) optimal control, which had globally optimal solutions (see Skelton 1988). The first two moments of the stochastic process (the mean and the trace of covariance) can be controlled with these methods, even if the distribution of the random variables involved is not Gaussian. Hence, LQG became just an acronym for the solution of quadratic functionals of control and state variables, even when the stochastic processes were not Gaussian. The label LQG was often used even for deterministic problems, where a time integral, rather than an expectation operator, was minimized, with given initial conditions or impulse excitations. These were formally called linear quadratic regulator (LQR) problems. Later the book Skelton (1988) gave the formal conditions under which the LQG and the LQR answers were numerically identical, and this particular version of LQR was called the *deterministic LQG*.

It was always recognized that the quadratic form of the state and control in the LQG problem was an artificial goal. The real control goals usually involved prespecified performance bounds on *each* of the outputs and bounds on *each* channel of the control and/or sensor channels. This leads to matrix inequalities (MIs) rather than a scalar minimization. While it was known early that *any* stabilizing linear controller could be obtained by some choice of weights in an LQG optimization problem (see Chap. 6 and references

in Skelton 1988), it was not known until the 1980s *what* particular choice of weights in LQG would yield a solution to multiple performance bounds on output and control (the matrix inequality (MI) problem). See early attempts in Skelton (1988), and see Zhu and Skelton (1992) and Zhu et al. (1997) for a globally convergent algorithm to find such LQG weights when the MI problem has a solution. Since then, rather than stating a minimization problem for a meaningless sum of outputs and inputs, linear control problems can now be stated simply in terms of norm bounds on *each* input vector and/or *each* output vector of the system (L_2 bounds, L_∞ bounds, or variance and covariance bounds). These advances led to the theory of covariance control. These *feasibility* problems are convex for state feedback or full-order output feedback controllers (the focus of this elementary introduction), and these can be solved using linear matrix inequalities (LMIs), as illustrated in this entry.

Perhaps the earliest book on LMI control methods was Boyd et al. (1994), but the results and notations used herein are taken from Skelton et al. (1998). Other important LMI papers and books can give the reader a broader background, including Iwasaki and Skelton (1994), Gahinet and Apkarian (1994), Scherer (1995); Scherer et al. (1997), de Oliveira et al. (2002), Li et al. (2008), de Oliveira and Skelton (2001), Camino et al. (2001, 2003a), Boyd and Vandenberghe (2004), Iwasaki et al. (2000), Khargonekar and Rotea (1991), Balakrishnan et al. (1994), Vandenberghe and Boyd (1996), Gahinet et al. (1995), and Dullerud and Paganini (2000).

Linear Matrix Equalities and Inequalities

A matrix equality is called linear matrix equality (LME) if the unknown matrix appears linearly in the equation. A linear matrix equality (LME) " $\mathbf{TGA} = \mathbf{\Theta}$ " may or may not have a solution for $\mathbf{G}$. For LMEs, there are only two questions to answer: (i) "Does there exist a solution?" and (ii) "What is the set of all solutions?" The answer to

question (i) is: “There exists a solution if and only if $\Gamma\Gamma^+ \Theta \Lambda^+ \Lambda = \Theta$.” The answer to question (ii) is: “ $\mathbf{G} = \Gamma^+ \Theta \Lambda^+ + \mathbf{Z} - \Gamma^+ \Gamma \mathbf{Z} \Lambda \Lambda^+$, where $\mathbf{Z}$ is arbitrary, and the $+$ symbol denotes Pseudo-Inverse.” LMI approaches employ the same two questions as LMEs, by formulating the necessary and sufficient conditions for the existence of an LMI solution and then to parametrize all solutions.

First, any matrix inequality is just a short-hand notation to represent a certain scalar inequality. For any square matrix $\mathbf{Q}$, the matrix inequality “ $\mathbf{Q} > \mathbf{0}$ ” means “the scalar $\mathbf{x}^T \mathbf{Q} \mathbf{x}$ is positive for all values of $\mathbf{x}$, except $\mathbf{x} = \mathbf{0}$.” Obviously this is a property of $\mathbf{Q}$, not $\mathbf{x}$, hence the abbreviated matrix notation $\mathbf{Q} > \mathbf{0}$. This matrix inequality is a linear matrix inequality (LMI), since the matrix unknown $\mathbf{Q}$ appears linearly in the inequality $\mathbf{Q} > \mathbf{0}$. Note also that any square matrix $\mathbf{Q}$ can be written as the sum of a symmetric matrix $\mathbf{Q}_s = \frac{1}{2}(\mathbf{Q} + \mathbf{Q}^T)$, and a skew-symmetric matrix $\mathbf{Q}_a = \frac{1}{2}(\mathbf{Q} - \mathbf{Q}^T)$, but $\mathbf{x}^T \mathbf{Q}_a \mathbf{x} = 0$, so only the symmetric part of the matrix $\mathbf{Q}$ affects the scalar $\mathbf{x}^T \mathbf{Q} \mathbf{x}$. We assume hereafter without loss of generality that $\mathbf{Q}$ is symmetric. The notation “ $\mathbf{Q} \geq \mathbf{0}$ ” means “the scalar $\mathbf{x}^T \mathbf{Q} \mathbf{x}$ cannot be negative for any $\mathbf{x}$.”

The answers to two questions of existence condition and set of all solutions for a particular LMI are summarized here. For any given matrices Γ , Λ , and Θ , the LMI :

$$\Gamma \mathbf{G} \Lambda + (\Gamma \mathbf{G} \Lambda)^T + \Theta < \mathbf{0}, \quad (1)$$

has a solution for matrix $\mathbf{G}$ if and only if the following two conditions hold:

$$\mathbf{U}_\Gamma^T \Theta \mathbf{U}_\Gamma < \mathbf{0}, \quad \text{or} \quad \Gamma \Gamma^T > \mathbf{0}, \quad (2)$$

$$\mathbf{V}_\Lambda^T \Theta \mathbf{V}_\Lambda < \mathbf{0}, \quad \text{or} \quad \Lambda^T \Lambda > \mathbf{0}. \quad (3)$$

where the left (right) null spaces of any matrix $\mathbf{B}$ is defined by matrices $\mathbf{U}_B$ ($\mathbf{V}_B$), where $\mathbf{U}_B^T \mathbf{B} = \mathbf{0}$, $\mathbf{U}_B^T \mathbf{U}_B > \mathbf{0}$, ($\mathbf{B} \mathbf{V}_B = \mathbf{0}$, $\mathbf{V}_B^T \mathbf{V}_B > \mathbf{0}$). If $\mathbf{G}$ exists, then one set of such $\mathbf{G}$ is given by

$$\mathbf{G} = -\rho \Gamma^T \Phi \Lambda^T (\Lambda \Phi \Lambda^T)^{-1}, \quad \Phi = (\rho \Gamma \Gamma^T - \Theta)^{-1}, \quad (4)$$

where $\rho > 0$ is an arbitrary scalar such that

$$\Phi = (\rho \Gamma \Gamma^T - \Theta)^{-1} > \mathbf{0}. \quad (5)$$

All $\mathbf{G}$ which solve the problem are given by Theorem 2.3.12 in Skelton et al. (1998). As elaborated in Chap. 9 of Skelton et al. (1998), 17 different control problems reduce to this *same* matrix inequality (1). Several examples from Skelton et al. (1998) are given in Sect. 4.

Lyapunov Equations and Related LMIs

Lyapunov proved that $\mathbf{x}(t)$ converges to zero if there exists a matrix $\mathbf{Q}$ such that two scalars have the property, $\mathbf{x}(t)^T \mathbf{Q} \mathbf{x}(t) > 0$ and $d/dt(\mathbf{x}^T(t) \mathbf{Q} \mathbf{x}(t)) < 0$, along the nonzero trajectory of a dynamic system (e.g., the system $\dot{\mathbf{x}} = \mathbf{A} \mathbf{x}$). That is, for any initial condition $\mathbf{x}(0)$ of the system $\dot{\mathbf{x}} = \mathbf{A} \mathbf{x}$, the state $\mathbf{x}(t)$ converges to zero, if and only if, there exists a matrix $\mathbf{Q}$ such that $\mathbf{Q} > \mathbf{0}$ and $\mathbf{Q} \mathbf{A} + \mathbf{A}^T \mathbf{Q} < \mathbf{0}$. The above two inequalities are LMIs (in the unknown matrix $\mathbf{Q}$), which proves the stability of the system.

LMIs are prevalent throughout the fundamental concepts of linear control theory, ranging from stability to controllability and observability, to robust and covariance control. For the linear system example, $\dot{\mathbf{x}} = \mathbf{A} \mathbf{x} + \mathbf{B} \mathbf{u}$ and $\mathbf{y} = \mathbf{C} \mathbf{x}$, the “Controllability Gramian”: $\mathbf{X} = \int_0^\infty e^{\mathbf{A}t} \mathbf{B} \mathbf{B}^T e^{\mathbf{A}^T t} dt > \mathbf{0}$ if and only if the pair $(\mathbf{A}, \mathbf{B})$ is controllable and $\mathbf{X}$ is bounded only if the controllable modes are asymptotically stable. If $\mathbf{X}$ exists, it satisfies $\mathbf{X} \mathbf{A}^T + \mathbf{A} \mathbf{X} + \mathbf{B} \mathbf{B}^T = \mathbf{0}$, and $\mathbf{X} > \mathbf{0}$ if and only if $(\mathbf{A}, \mathbf{B})$ is a controllable pair. Likewise, if the “Observability Gramian” $\mathbf{Q} = \int_0^\infty e^{\mathbf{A}^T t} \mathbf{C}^T \mathbf{C} e^{\mathbf{A}t} dt > \mathbf{0}$ exists, it satisfies $\mathbf{Q} \mathbf{A} + \mathbf{A}^T \mathbf{Q} + \mathbf{C}^T \mathbf{C} = \mathbf{0}$ if and only if the matrix pair $(\mathbf{A}, \mathbf{C})$ is observable. Note also that the matrix pair $(\mathbf{A}, \mathbf{B})$ is controllable for any $\mathbf{A}$ if $\mathbf{B} \mathbf{B}^T > \mathbf{0}$, and the matrix pair $(\mathbf{A}, \mathbf{C})$ is observable for any $\mathbf{A}$ if $\mathbf{C}^T \mathbf{C} > \mathbf{0}$. Hence, the existence of $\mathbf{Q} > \mathbf{0}$ or $\mathbf{X} > \mathbf{0}$ satisfying either $(\mathbf{Q} \mathbf{A} + \mathbf{A}^T \mathbf{Q} < \mathbf{0})$ or $(\mathbf{A} \mathbf{X} + \mathbf{X} \mathbf{A}^T < \mathbf{0})$ is equivalent to the asymptotic stability of the

system. The same LMIs were obtained using the Lyapunov stability results.

It should now be clear that the set of all stabilizing state feedback controllers, $\mathbf{u} = \mathbf{G}\mathbf{x}$, is parametrized by the inequalities $\mathbf{Q} > \mathbf{0}$, $\mathbf{Q}(\mathbf{A} + \mathbf{B}\mathbf{G}) + (\mathbf{A} + \mathbf{B}\mathbf{G})^T\mathbf{Q} < \mathbf{0}$. This is a matrix inequality (product of the two unknowns $\mathbf{Q}$ and $\mathbf{G}$) which can be converted to an LMI using standard techniques.

Other than providing Controllability Gramian and the condition for asymptotic stability, the Lyapunov equation $\mathbf{X}\mathbf{A}^T + \mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{B}^T = \mathbf{0}$ has two more interpretations.

1. **Stochastic Interpretations** : The matrix solution $\mathbf{X}$ for equation $\mathbf{X}\mathbf{A}^T + \mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{B}^T = \mathbf{0}$ can represent the steady-state covariance matrix ($\mathbf{X} = \mathbb{E}[\mathbf{x}\mathbf{x}^T]$) in the presence of zero mean white noise disturbance of unit intensity $\mathbf{w}$ in $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{w}$. Moreover, the LMI $\bar{\mathbf{X}}\mathbf{A}^T + \mathbf{A}\bar{\mathbf{X}} + \mathbf{B}\mathbf{B}^T < \mathbf{0}$ can be solved to bound the steady-state covariance matrix $\mathbf{X} < \bar{\mathbf{X}}$, which in turn can be used to bound the steady-state output covariance $\mathbf{Y} = \mathbb{E}[\mathbf{y}\mathbf{y}^T] = \mathbf{C}\mathbf{X}\mathbf{C}^T < \bar{\mathbf{Y}}$ for the output equation $\mathbf{y} = \mathbf{C}\mathbf{x}$.
2. **Deterministic Interpretations** : The matrix $\mathbf{X}$ can also be interpreted as

$$\mathbf{X} = \sum_{i=1}^{n_w} \int_0^\infty \mathbf{x}(i, t) \mathbf{x}^T(i, t) dt,$$

where $\mathbf{x}(i, t)$ represents the solution of the state equation when only the i^{th} excitation ($\mathbf{w}_i = \delta(t)$) is applied, for the system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{w}$. Notice that $tr(\mathbf{X}) = \sum_{i=1}^{n_w} \|\mathbf{x}(i, \cdot)\|_{L_2}^2$, where $tr(\cdot)$ is the trace operator and $\|\mathbf{x}\|_{L_2}^2$ represents the energy in the signal $\mathbf{x}$. Also notice that $tr(\mathbf{C}\mathbf{X}\mathbf{C}^T) = \sum_{i=1}^{n_w} \|\mathbf{y}(i, \cdot)\|_{L_2}^2$, where $\mathbf{y}(i, \cdot)$ is the output signal for $\mathbf{y} = \mathbf{C}\mathbf{x}$. A time-domain interpretation of the H_2 norm of the transfer matrix $\mathbf{T}(s)$ is also given by $\|\mathbf{T}\|_{H_2}^2 = \sum_{i=1}^{n_w} \|\mathbf{y}(i, \cdot)\|_{L_2}^2 = tr(\mathbf{C}\mathbf{X}\mathbf{C}^T)$. This interpretation forms the basis to provide solutions to LQR, H_2 , and L_2 control problems.

For a rigorous equivalence of the deterministic and stochastic interpretations, see Skelton (1988). These different interpretations of the Lyapunov equation led to solve many control problems using the same LMI (Skelton et al. 1998).

Many Control Problems Reduce to the Same LMI

Consider the feedback control system

$$\begin{bmatrix} \dot{\mathbf{x}}_p \\ \mathbf{y} \\ \mathbf{z} \end{bmatrix} = \begin{bmatrix} \mathbf{A}_p & \mathbf{D}_p & \mathbf{B}_p \\ \mathbf{C}_p & \mathbf{D}_y & \mathbf{B}_y \\ \mathbf{M}_p & \mathbf{D}_z & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{x}_p \\ \mathbf{w} \\ \mathbf{u} \end{bmatrix}, \quad (6)$$

$$\begin{bmatrix} \mathbf{u} \\ \dot{\mathbf{x}}_c \end{bmatrix} = \begin{bmatrix} \mathbf{D}_c & \mathbf{C}_c \\ \mathbf{B}_c & \mathbf{A}_c \end{bmatrix} \begin{bmatrix} \mathbf{z} \\ \mathbf{x}_c \end{bmatrix} = \mathbf{G} \begin{bmatrix} \mathbf{z} \\ \mathbf{x}_c \end{bmatrix}, \quad (7)$$

where $\mathbf{z}$ is the measurement vector, $\mathbf{y}$ is the output to be controlled, $\mathbf{u}$ is the control vector, $\mathbf{x}_p$ is the plant state vector, $\mathbf{x}_c$ is the state of the controller, and $\mathbf{w}$ is the external disturbance. By defining the matrices

$$\begin{aligned} \mathbf{x} &= \begin{bmatrix} \mathbf{x}_p \\ \mathbf{x}_c \end{bmatrix}, \quad \begin{bmatrix} \mathbf{A}_{cl} & \mathbf{B}_{cl} \\ \mathbf{C}_{cl} & \mathbf{D}_{cl} \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{A} & \mathbf{D} \\ \mathbf{C} & \mathbf{F} \end{bmatrix} + \begin{bmatrix} \mathbf{B} \\ \mathbf{H} \end{bmatrix} \mathbf{G} [\mathbf{M} \mathbf{E}], \end{aligned} \quad (8)$$

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{B}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix},$$

$$\mathbf{M} = \begin{bmatrix} \mathbf{M}_p & \mathbf{I} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}, \quad \mathbf{D} = \begin{bmatrix} \mathbf{D}_p \\ \mathbf{0} \end{bmatrix}, \mathbf{E} = \begin{bmatrix} \mathbf{D}_z \\ \mathbf{0} \end{bmatrix} \quad (9)$$

$$\mathbf{C} = [\mathbf{C}_p \mathbf{0}], \quad \mathbf{H} = [\mathbf{B}_y \mathbf{0}], \quad \mathbf{F} = \mathbf{D}_y, \quad (10)$$

one can write the closed-loop system dynamics in the form

$$\begin{bmatrix} \dot{\mathbf{x}} \\ \mathbf{y} \end{bmatrix} = \begin{bmatrix} \mathbf{A}_{cl} & \mathbf{B}_{cl} \\ \mathbf{C}_{cl} & \mathbf{D}_{cl} \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{w} \end{bmatrix}. \quad (11)$$

Often we seek to characterize the set of all controllers $\mathbf{G}$ to satisfy the given upper bounds on the output and input covariances, $\mathbb{E}[\mathbf{y}\mathbf{y}^T] \leq \bar{\mathbf{Y}}$, $\mathbb{E}[\mathbf{u}\mathbf{u}^T] \leq \bar{\mathbf{U}}$. Such problems are called *covariance* control problems (see Chap. 6 of Skelton

et al. 1998), where $\mathbb{E}$ represents the steady-state expectation operator in the stochastic case (i.e., when $\mathbf{w}$ is white noise), and in the deterministic case, $\mathbb{E}$ represents the infinite integral of the matrix $[\mathbf{y}\mathbf{y}^T]$. The math remains the same in each case, with appropriate interpretations of certain matrices as explained in the previous section.

Moreover, the *same* math, the *same* matrix inequality “ $\mathbf{\Gamma}\mathbf{G}\mathbf{\Lambda} + (\mathbf{\Gamma}\mathbf{G}\mathbf{\Lambda})^T + \mathbf{\Theta} < \mathbf{0}$ ” solves 17 different control problems (using either state feedback or full-order dynamic controllers) by defining the appropriate $\mathbf{\Theta}$, $\mathbf{\Lambda}$, and $\mathbf{\Gamma}$. This includes the characterization of all stabilizing controllers, covariance control, H_∞ control, L_∞ control, LQG control, and H_2 control, including their discrete versions. Several examples from Skelton et al. (1998) follow.

Stabilizing Control

There exists a controller $\mathbf{G}$ that stabilizes the system (6) if and only if (2) and (3) hold, where the matrices are defined by

$$[\mathbf{\Gamma}|\mathbf{\Lambda}^T|\mathbf{\Theta}] = [\mathbf{B}|\mathbf{X}\mathbf{M}^T|\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^T]. \quad (12)$$

One can also write such results in another way, as in Corollary 6.2.1 of Skelton et al. (1998, p. 135): There exists a control of the form $\mathbf{u} = \mathbf{G}\mathbf{x}$ that can stabilize the system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$ if and only if there exists a matrix $\mathbf{X} > \mathbf{0}$ satisfying $\mathbf{B}^\perp(\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^T)(\mathbf{B}^\perp)^T < \mathbf{0}$, where $\mathbf{B}^\perp$ denotes the left null space of $\mathbf{B}$. In this case all stabilizing controllers may be parametrized by $\mathbf{G} = -\mathbf{B}^T\mathbf{P} + \mathbf{L}\mathbf{Q}^{1/2}$, for any $\mathbf{Q} > \mathbf{0}$ and a $\mathbf{P} > \mathbf{0}$ satisfying $\mathbf{P}\mathbf{A} + \mathbf{A}^T\mathbf{P} - \mathbf{P}\mathbf{B}\mathbf{B}^T\mathbf{P} + \mathbf{Q} = \mathbf{0}$. The matrix $\mathbf{L}$ is any matrix that satisfies the norm bound $\|\mathbf{L}\| < 1$. Youla et al. (1976) provided a parametrization of the set of all stabilizing controllers, but the parametrization was infinite dimensional (as it did not impose any restriction on the order or form of the controller). So for finite calculations, one had to truncate the set to a finite number before optimization or stabilization started. As noted above, on the other hand, all stabilizing state feedback controllers $\mathbf{G}$ can be parametrized in terms of an arbitrary but finite-dimensional norm-bounded matrix $\mathbf{L}$. Similar results apply for

the dynamic controllers of any fixed order (see Chap. 6 in Skelton et al. 1998).

Covariance Upper Bound Control

In the system (6), suppose that $\mathbf{D}_y = \mathbf{0}$, $\mathbf{B}_y = \mathbf{0}$ and that $\mathbf{w}$ is zero-mean white noise with intensity $\mathbf{I}$. Let a required upper bound $\bar{\mathbf{Y}} > \mathbf{0}$ on the steady-state output covariance $\mathbf{Y} = \mathbb{E}[\mathbf{y}\mathbf{y}^T]$ be given. The following statements are equivalent:

- (i) There exists a controller $\mathbf{G}$ that solves the covariance upper bound control problem $\mathbf{Y} < \bar{\mathbf{Y}}$.
- (ii) There exists a matrix $\mathbf{X} > \mathbf{0}$ such that $\mathbf{Y} = \mathbf{C}\mathbf{X}\mathbf{C}^T < \bar{\mathbf{Y}}$ and (2) and (3) hold, where the matrices are defined by

$$[\mathbf{\Gamma}|\mathbf{\Lambda}^T|\mathbf{\Theta}] = \begin{bmatrix} \mathbf{B} & \mathbf{X}\mathbf{M}^T & \mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^T & \mathbf{D} \\ \mathbf{0} & \mathbf{E}^T & \mathbf{D}^T & -\mathbf{I} \end{bmatrix}. \quad (13)$$

Proof is provided by Theorem 9.1.2 in Skelton et al. (1998).

Linear Quadratic Regulator

Consider the linear time-invariant system (6). Suppose that $\mathbf{D}_y = \mathbf{0}$, $\mathbf{D}_z = \mathbf{0}$ and that $\mathbf{w}$ is the impulsive disturbance $\mathbf{w}(t) = \mathbf{w}_0\delta(t)$. Let a performance bound $\gamma > 0$ be given, where the required performance is to keep the integral squared output less than the prespecified value $\|\mathbf{y}\|_{L_2} < \gamma$ for any vector $\mathbf{w}_0$ such that $\mathbf{w}_0^T\mathbf{w}_0 \leq 1$, and $\mathbf{x}_0 = \mathbf{0}$. This problem is labeled as linear quadratic regulator (LQR). The following statements are equivalent:

- (i) There exists a controller $\mathbf{G}$ that solves the LQR problem.
- (ii) There exists a matrix $\mathbf{Y} > \mathbf{0}$ such that $\|\mathbf{D}^T\mathbf{Y}\mathbf{D}\| < \gamma^2$ and (2) and (3) hold, where the matrices are defined by

$$[\mathbf{\Gamma}|\mathbf{\Lambda}^T|\mathbf{\Theta}] = \begin{bmatrix} \mathbf{Y}\mathbf{B} & \mathbf{M}^T & \mathbf{Y}\mathbf{A} + \mathbf{A}^T\mathbf{Y} & \mathbf{M}^T \\ \mathbf{H} & \mathbf{0} & \mathbf{M} & -\mathbf{I} \end{bmatrix}. \quad (14)$$

Proof is provided by Theorem 9.1.3 in Skelton et al. (1998).

H-Infinity Control

LMI techniques provided the first papers to solve the general H_∞ problem, without any restrictions on the plant. See Iwasaki and Skelton (1994) and Gahinet and Apkarian (1994). Let the closed-loop transfer matrix from $\mathbf{w}$ to $\mathbf{y}$ with the controller in (6) be denoted by $\mathbf{T}(s)$:

$$\mathbf{T}(s) = \mathbf{C}_{cl}(s\mathbf{I} - \mathbf{A}_{cl})^{-1}\mathbf{B}_{cl} + \mathbf{D}_{cl}. \quad (15)$$

The H_∞ control problem can be defined as follows:

Let a performance bound $\gamma > 0$ be given. Determine whether or not there exists a controller $\mathbf{G}$ in (6) which asymptotically stabilizes the system and yields the closed-loop transfer matrix (15) such that the peak value of the frequency response is less than γ . That is, $\|\mathbf{T}\|_{H_\infty} = \sup \|\mathbf{T}(j\omega)\| < \gamma$.

The following statements are equivalent:

- (i) A controller $\mathbf{G}$ solves the H_∞ control problem.
- (ii) There exists a matrix $\mathbf{X} > \mathbf{0}$ such that (2) and (3) hold, where

$$[\Gamma | \Lambda^T | \Theta] = \begin{bmatrix} \mathbf{B} & \mathbf{X}\mathbf{M}^T & \mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^T & \mathbf{X}\mathbf{C}^T & \mathbf{D} \\ \mathbf{H} & \mathbf{0} & \mathbf{C}\mathbf{X} & -\gamma\mathbf{I} & \mathbf{F} \\ \mathbf{0} & \mathbf{E}^T & \mathbf{D}^T & \mathbf{F}^T & -\gamma\mathbf{I} \end{bmatrix}. \quad (16)$$

Proof is provided by Theorem 9.1.5 in Skelton et al. (1998).

L-Infinity Control

The peak value of the frequency response is controlled by the above H_∞ controller. A similar theorem can be written to control the peak in the time domain. Define $\sup[\mathbf{y}(t)^T\mathbf{y}(t)] = \|\mathbf{y}\|_{L_\infty}^2$, and let the statement $\|\mathbf{y}\|_{L_\infty} < \gamma$ mean that the peak value of $[\mathbf{y}(t)^T\mathbf{y}(t)]$ is less than γ^2 . Suppose that $\mathbf{D}_y = \mathbf{0}$ and $\mathbf{B}_y = \mathbf{0}$. There exists a controller $\mathbf{G}$ which maintains $\|\mathbf{y}\|_{L_\infty} < \gamma$ in the presence of any energy-bounded input $\mathbf{w}(t)$ (i.e., $\int_0^\infty \mathbf{w}^T\mathbf{w}dt \leq 1$) if and only if there exists a matrix $\mathbf{X} > \mathbf{0}$ such that $\mathbf{C}\mathbf{X}\mathbf{C}^T < \gamma^2\mathbf{I}$ and (2) and (3) hold, where

$$[\Gamma | \Lambda^T | \Theta] = \begin{bmatrix} \mathbf{B} & \mathbf{X}\mathbf{M}^T & \mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^T & \mathbf{D} \\ \mathbf{0} & \mathbf{E}^T & \mathbf{D}^T & -\gamma\mathbf{I} \end{bmatrix}. \quad (17)$$

Proof is provided by Theorem 9.1.4 in Skelton et al. (1998). Note that the L_∞ control and covariance upper bound control have exactly the same final mathematical result as explained in Sect. 3.

Information Architecture in Estimation and Control Problems

In a typical “control problem” that occupies most research literature, the sensors and actuators have already been selected. Yet the selection of sensors and actuators and their locations greatly affect the ability of the control system to do its job efficiently. Perhaps in one location a high-precision sensor is needed, and in another location high precision is not needed, and paying for high precision in that location would, therefore, be a waste of resources. These decisions must be influenced by the control dynamics which are yet to be designed. How does one know where to effectively spend money to improve the system? To answer this question, we must optimize the information architecture (sensor/actuator precision) jointly with the control law.

Traditionally, with full-order controllers, and *prespecified* sensor/actuator instruments (with specified precisions), the problem of designing a controller to constrain the upper bounds on the covariance of output error and control signal is a well-known solved convex problem (which means it can be converted to an LMI problem if desired), see Scherer et al. (1997) and Chap. 6 of Skelton et al. (1998). If we enlarge the domain of design freedom to include sensor/actuator precisions, it is not obvious whether the feasibility problem is convex or not. The following shows that this problem of including the sensor/actuator precisions within the control design problem is indeed convex (Li et al. 2008).

Let us consider the linear control system (6)–(11). Suppose that $\mathbf{D}_y = \mathbf{0}$, $\mathbf{B}_y = \mathbf{0}$, $\mathbf{D}_p = [\mathbf{D}_{pn} \ \mathbf{D}_a \ 0]$, and $\mathbf{D}_z = [0 \ 0 \ \mathbf{D}_s]$.

The vector $\mathbf{w}^T = [\mathbf{w}_p^T \ \mathbf{w}_a^T \ \mathbf{w}_s^T]$ contains process noise $\mathbf{w}_p$, actuator noise $\mathbf{w}_a$, and sensor noise $\mathbf{w}_s$. These disturbances are modeled as independent zero mean white noises with intensities $\mathbf{W}_p$, $\mathbf{W}_a$, and $\mathbf{W}_s$, respectively. The process noise intensity $\mathbf{W}_p$ is assumed to be known and fixed. The actuator and sensor precisions are defined as the inverse of the noise intensity (or variance in the discrete-time case) in each channel:

$$\text{diag}(\boldsymbol{\gamma}_a) \triangleq \boldsymbol{\Gamma}_a \triangleq \mathbf{W}_a^{-1}, \quad \text{diag}(\boldsymbol{\gamma}_s) \triangleq \boldsymbol{\Gamma}_s \triangleq \mathbf{W}_s^{-1}. \quad (18)$$

Assume that the price of each actuator/sensor is proportional to the precision associated with that instrument. Therefore, the total cost of all actuators and sensors is

$$\$ = \mathbf{p}_a^T \boldsymbol{\gamma}_a + \mathbf{p}_s^T \boldsymbol{\gamma}_s, \quad (19)$$

where $\mathbf{p}_a$ and $\mathbf{p}_s$ are vectors containing the price per unit of actuator precision and sensor precision, respectively.

Let $\bar{\$}$ represent the budget; the allowed upper bound on sensor/actuator costs, and $\bar{\boldsymbol{\gamma}}_a$ and $\bar{\boldsymbol{\gamma}}_s$ represent the limit on available precisions of actuators and sensors. Then, there exists a dynamic controller $\mathbf{G}$ and choices of sensor/actuator precisions $\boldsymbol{\Gamma}_s$, $\boldsymbol{\Gamma}_a$ that satisfy the constraints

$$\begin{aligned} \$ &< \bar{\$}, \quad \boldsymbol{\gamma}_a < \bar{\boldsymbol{\gamma}}_a, \quad \boldsymbol{\gamma}_s < \bar{\boldsymbol{\gamma}}_s, \\ \mathbb{E}[\mathbf{u}\mathbf{u}^T] &< \bar{\mathbf{U}}, \quad \mathbb{E}[\mathbf{y}\mathbf{y}^T] < \bar{\mathbf{Y}}, \end{aligned} \quad (20)$$

if and only if there exist matrices $\mathbf{L}$, $\mathbf{F}$, $\mathbf{Q}$, $\mathbf{X}$, and $\mathbf{Z}$ and vectors $\boldsymbol{\gamma}_a$ and $\boldsymbol{\gamma}_s$ such that the following LMIs are satisfied

$$\begin{aligned} \mathbf{p}_a^T \boldsymbol{\gamma}_a + \mathbf{p}_s^T \boldsymbol{\gamma}_s &< \bar{\$}, \\ \boldsymbol{\gamma}_a &< \bar{\boldsymbol{\gamma}}_a, \quad \boldsymbol{\gamma}_s < \bar{\boldsymbol{\gamma}}_s, \\ \begin{bmatrix} \bar{\mathbf{Y}} & \mathbf{C}_p \mathbf{X} \mathbf{C}_p \\ (\mathbf{C}_p \mathbf{X})^T & \mathbf{X} & \mathbf{I} \\ \mathbf{C}_p^T & \mathbf{I} & \mathbf{Z} \end{bmatrix} &> \mathbf{0}, \end{aligned} \quad (21)$$

$$\begin{bmatrix} \bar{\mathbf{U}} & \mathbf{L} & \mathbf{0} \\ \mathbf{L}^T & \mathbf{X} & \mathbf{I} \\ \mathbf{0} & \mathbf{I} & \mathbf{Z} \end{bmatrix} > \mathbf{0}, \quad \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{12}^T & \Phi_{22} \end{bmatrix} < \mathbf{0}, \quad (22)$$

$$\begin{aligned} \Phi_{11} &= \boldsymbol{\phi} + \boldsymbol{\phi}^T, \\ \boldsymbol{\phi} &= \begin{bmatrix} \mathbf{A}_p \mathbf{X} + \mathbf{B}_p \mathbf{L} & \mathbf{A}_p \\ \mathbf{Q} & \mathbf{Z} \mathbf{A}_p + \mathbf{F} \mathbf{M}_p \end{bmatrix}, \\ \Phi_{12} &= \begin{bmatrix} \mathbf{D}_{pn} & \mathbf{D}_a & \mathbf{0} \\ \mathbf{Z} \mathbf{D}_{pn} & \mathbf{Z} \mathbf{D}_a & \mathbf{F} \mathbf{D}_s \end{bmatrix}, \end{aligned} \quad (23)$$

$$\Phi_{22} = \begin{bmatrix} -\mathbf{W}_p^{-1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{\Gamma}_a & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & -\boldsymbol{\Gamma}_s \end{bmatrix}. \quad (24)$$

Note that the matrix inequalities (21)–(24) are LMIs in the collection of variables $(\mathbf{L}, \mathbf{F}, \mathbf{Q}, \mathbf{X}, \mathbf{Z}, \boldsymbol{\gamma}_a, \boldsymbol{\gamma}_s)$, hence, the joint control/sensor/actuator design is a convex problem.

After a solution $(\mathbf{L}, \mathbf{F}, \mathbf{Q}, \mathbf{X}, \mathbf{Z}, \boldsymbol{\gamma}_a, \boldsymbol{\gamma}_s)$ is found using the LMIs (21)–(24), then the problem (20) is solved for the controller as

$$\begin{aligned} \mathbf{G} &= \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{V}_l^{-1} & -\mathbf{V}_l^{-1} \mathbf{Z} \mathbf{B}_p \end{bmatrix} \begin{bmatrix} \mathbf{Q} - \mathbf{Z} \mathbf{A}_p \mathbf{X} & \mathbf{F} \\ \mathbf{L} & \mathbf{0} \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{0} & \mathbf{V}_r^{-1} \\ \mathbf{I} & -\mathbf{M}_p \mathbf{X} \mathbf{V}_r^{-1} \end{bmatrix}, \end{aligned} \quad (25)$$

where $\mathbf{V}_l$ and $\mathbf{V}_r$ are left and right factors of the matrix $\mathbf{I} - \mathbf{Z}\mathbf{X}$ (which can be found from the singular value decomposition $\mathbf{I} - \mathbf{Z}\mathbf{X} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T = (\mathbf{U}\boldsymbol{\Sigma}^{1/2})(\boldsymbol{\Sigma}^{1/2}\mathbf{V}^T) = (\mathbf{V}_l)(\mathbf{V}_r)$).

To emphasize the theme of this entry, to relate optimization to LMIs, we note that three optimization problems present themselves in the above problem with three constraints: control effort $\bar{\mathbf{U}}$, output performance $\bar{\mathbf{Y}}$, and instrument costs $\bar{\$}$. To solve optimization problems, one can fix any two of these prespecified upper bounds and iteratively reduce the level set value of the third “constraint” until feasibility is lost. This process minimizes the resource expressed by the third constraint, while enforcing the other two constraints.

As an example, if the cost is not a concern, one can always set large limits for $\bar{\$}$ and discover the best assignment of sensor/actuator precisions for

the specified performance requirements. The precisions produced by the algorithm are the values $\gamma_{a_i}, \gamma_{s_i}$, produced from the solution (21)–(24), where the observed rankings $\gamma_i > \gamma_j > \gamma_k > \dots$ indicate which sensors or actuators are most critical to the required performance constraints ($\bar{U}, \bar{Y}, \bar{\$}$). If any precision γ_n is essentially zero, compared to other required precisions, then the math is asserting that the information from this sensor (n) is not important for the control objectives specified, or the control signals through this actuator channel (n) are ineffective in controlling the system to these specifications. This information leads us to a technique for choosing the best sensor actuators and their location.

The previous discussion provides the precision (γ_i) required of each sensor and each actuator in the system. Our final application of this theory locates sensors and actuators in a large-scale system, by discarding the least effective ones. While the above method of selecting the precision of the instruments is proven to be a convex problem, the problem of deleting a sensor/actuator is not a convex problem. Suppose we solve the stated feasibility problem above, by starting with the entire admissible set of sensors and actuators. For example, in a flexible structure control problem, we might not know whether to place a rate sensor or displacement sensors at a given location, so we add both. We might not know whether to use torque or force actuators, so we add both. We fill up the system with the feasible set of possibilities and let the above precision rankings (available after the above LMI problem is solved) reveal how much precision is needed at each location and for each sensor/actuator. If the revealed required precision of any sensor or actuator is essentially zero, one can delete this instrument with impunity. Likewise, if the precision required of any instrument is insignificant compared to others (say $\gamma_i > \gamma_j > \gamma_k > \dots \gg \gamma_n$), then we shall take the ad-hoc decision to delete it, even though this step causes our problem of selecting which sensors and actuators to remove from the admissible set to be a non-convex problem. Our method of selecting critical sensors and actuators is summarized as follows: (i) For the entire set of admissible sensors and actuators,

solve the LMIs from the convex “Information Architecture” problem defined above. (ii) Delete the sensor or actuator requiring insignificant precision from step (i), if any. (iii) Repeat the LMI problem in step (i) with one less sensor or actuator. (iv) Continue deleting sensors/actuators in this manner until feasibility of the problem is lost. Then take the result of the previous iteration as the final answer for the specific problem specified by the allowable bounds ($\bar{\$}, \bar{U}, \bar{Y}$).

The major contribution of the above algorithm has been to extend control theory to include “Information Precision and Architecture” in control design and to prove that the information precision and control design is jointly a convex problem. This enlarges the set of solved linear control problems, from solutions of linear controllers with sensors/actuators prespecified to solutions which specify the sensor/actuator requirements jointly with the control solution.

While this section provides a framework for combined instrument and control design, it is possible to also add plant parameters into the domain of the system design problem. Let the vector α represent the plant parameters that will be optimized along with the controller matrix $\mathbf{G}$ and the sensor/actuator precision (γ) to meet certain performance requirements of input/output covariance bounds; as above, this integrated design is not a convex problem, but one can add a convexifying potential function which generates a convex subproblem (Camino et al. 2003b). Then, iteration over that convex subproblem is guaranteed to reach a stationary solution for the following problem (Goyal and Skelton 2019):

$$\mathbf{E}_p(\alpha)\dot{\mathbf{x}}_p = \mathbf{A}_p(\alpha)\mathbf{x}_p + \mathbf{D}_p(\alpha)\mathbf{w} + \mathbf{B}_p\mathbf{u},$$

$$\mathbf{y} = \mathbf{C}_p(\alpha)\mathbf{x}_p, \quad (26)$$

$$\mathbb{E}[\mathbf{u}\mathbf{u}^T] < \bar{\mathbf{U}}, \quad \mathbb{E}[\mathbf{y}\mathbf{y}^T] < \bar{\mathbf{Y}}. \quad (27)$$

Summary

Feasibility constraints and LMI techniques provide more powerful tools for designing dynamic

linear systems than techniques that minimize a scalar functional for optimization, since multiple goals (bounds) can be achieved, where *each* of the output and input norms can be bounded. If the problem can be reduced to a set of LMIs to solve, then convexity is proven, and standard LMI software toolboxes are available to solve it. Failure to reduce the problem to LMIs does not imply non-convexity of the problem, but computer-assisted methods for convex problems are available to avoid the search for LMIs. These feasibility problems also allow for optimization. Optimization can also be achieved with LMI methods by reducing the level set for one of the bounds while maintaining all the other bounds. This level-set is iteratively reduced after solving a convex problem at a given level-set. Continue reducing the level-set to find the smallest level-set that allows a solution to the convex problem.

A most amazing fact is that most of the common linear control design problems all reduce to exactly the *same* LMI. Such equivalent problems include: (i) the set of all stabilizing controllers, (ii) LQR, (iii) LQG, (iv) the set of all H_∞ controllers, (v) the set of all L_∞ controllers, (vi) positive real control design, (vii) pole assignment controllers, (viii) covariance control design, and the robust and discrete versions of these problems. Seventeen different control problems have been found to be equivalent to solving exactly the same LMI, by substituting appropriate matrix coefficients.

LMI techniques extend the range of solvable system design problems that are globally solved, and many of these problems are not even control problems. For example, the following problem reduces to an LMI: *Find the best digital computer simulation of a physical system, such that the errors of the simulation (introduced by errors in model order and errors introduced by computational roundoff errors) are limited to a specified covariance upperbound.*

By integrating information architecture and control design, one can use LMIs to simultaneously choose the control gains and the precision required of all sensor/actuators and all computer computations, to satisfy the closed-loop performance constraints. These techniques

can be used to select the information (with precision requirements) required to solve a control or estimation problem, using the most economic solution. Moreover, a suboptimal solution of integrated plant, control, and information architecture design can also be found by iterating over a set of convexified LMIs. This allows for one further step toward a system design approach to integrate multiple disciplines.

Linear Quadratic Optimal Control

H.L. Trentelman

Johann Bernoulli Institute for Mathematics and Computer Science, University of Groningen, Groningen, AV, The Netherlands

Abstract

Linear quadratic optimal control is a collective term for a class of optimal control problems involving a linear input-state-output system and a cost functional that is a quadratic form of the state and the input. The aim is to minimize this cost functional over a given class of input functions. The optimal input depends on the initial condition, but can be implemented by means of a state feedback control law independent of the initial condition. Both the feedback gain and the optimal cost can be computed in terms of solutions of Riccati equations.

Keywords

Algebraic riccati equation · Finite horizon · Infinite horizon · Linear systems · Optimal control · Quadratic cost functional · Riccati differential equation

Introduction

Linear quadratic optimal control is a generic term that collects a number of optimal control problems for linear input-state-output systems in which a quadratic cost functional is minimized

over a given class of input functions. This functional is formed by integrating a quadratic form of the state and the input over a finite or an infinite time interval. Minimizing the energy of the output over a finite or infinite time interval can be formulated in this framework and in fact provides a major motivation for this class of optimal control problems. A common feature of the solutions to the several versions of the problem is that the optimal input functions can be given in the form of a linear state feedback control law. This makes it possible to implement the optimal controllers as a feedback loop around the system. Another common feature is that the optimal value of the cost functional is a quadratic form of the initial condition on the system. This quadratic form is obtained by taking the appropriate solution of a Riccati differential equation or algebraic Riccati equation associated with the system.

Systems with Inputs and Outputs

Consider the continuous-time, linear time-invariant input-output system in state space form represented by

$$\dot{x}(t) = Ax(t) + Bu(t), \quad z(t) = Cx(t) + Du(t). \quad (1)$$

This system will be referred to as Σ . In (1), A , B , C , and D are maps between suitable spaces (or matrices of suitable dimensions) and the functions x , u , and z are considered to be defined on the real axis $\mathbb{R}$ or on any subinterval of it. In particular, one often assumes the domain of definition to be the nonnegative part of $\mathbb{R}$. The function u is called the *input*, and its values are assumed to be given from outside the system. The class of admissible input functions will be denoted $\mathbf{U}$. Often, $\mathbf{U}$ will be the class of piecewise continuous or locally integrable functions, but for most purposes, the exact class from which the input functions are chosen is not important. We will assume that input functions take values in an m -dimensional space $\mathcal{U}$, which we often identify with $\mathbb{R}^m$. The variable x is called the *state variable* and it is assumed to take values in an n -dimensional space $\mathcal{X}$. The space $\mathcal{X}$ will be called

the *state space*. It will usually be identified with $\mathbb{R}^n$. Finally, z is called the *to be controlled output* of the system and takes values in a p -dimensional space $\mathcal{Z}$, which we identify with $\mathbb{R}^p$. The solution of the differential equation of Σ with initial value $x(0) = x_0$ will be denoted as $x_u(t, x_0)$. It can be given explicitly using the variation-of-constants formula (see Trentelman et al. 2001, p. 38). The set of eigenvalues of a given matrix M is called the *spectrum* of M and is denoted by $\sigma(M)$. The system (1) is called *stabilizable* if there exists a map (matrix of suitable dimensions) F such that $\sigma(A + BF) \subset \mathbb{C}^-$. Here, $\mathbb{C}^-$ denotes the open left half complex plane, i.e., $\{\lambda \in \mathbb{C} \mid \operatorname{Re}(\lambda) < 0\}$. We often express this property by saying that the pair (A, B) is stabilizable.

The Linear Quadratic Optimal Control Problem

Assume that our aim is to keep all components of the output $z(t)$ as small as possible, for all $t \geq 0$. In the ideal situation, with initial state $x(0) = 0$, the uncontrolled system (with control input $u = 0$) evolves along the stationary solution $x(t) = 0$. Of course, the output $z(t)$ will then also be equal to zero for all t . If, however, at time $t = 0$ the state of the system is perturbed to, say, $x(0) = x_0$, with $x_0 \neq 0$, then the uncontrolled system will evolve along a state trajectory unequal to the stationary zero solution, and we will get $z(t) = Ce^{At}x_0$. To remedy this, from time $t = 0$ on, we can apply an input function u , so that for $t \geq 0$ the corresponding output becomes equal to $z(t) = Cx_u(t, x_0) + Du(t)$. Keeping in mind that we want the output $z(t)$ to be as small as possible for all $t \geq 0$, we can measure its size by the quadratic cost functional

$$J(x_0, u) = \int_0^\infty \|z(t)\|^2 dt, \quad (2)$$

where $\|\cdot\|$ denotes the Euclidean norm. Our aim to keep the values of the output as small as possible can then be expressed as requiring this integral to be as small as possible by suitable

choice of input function u . In this way we arrive at the *linear quadratic optimal control problem*:

Problem 1 Consider the system $\Sigma : \dot{x}(t) = Ax(t) + Bu(t)$, $z(t) = Cx(t) + Du(t)$. Determine for every initial state x_0 an input $u \in \mathbf{U}$ (a space of functions $[0, \infty) \rightarrow \mathcal{U}$) such that

$$J(x_0, u) := \int_0^\infty \|z(t)\|^2 dt \quad (3)$$

is minimal. Here $z(t)$ denotes the output trajectory $z_u(t, x_0)$ of Σ corresponding to the initial state x_0 and input function u .

Since the system is linear and the integrand in the cost functional is a quadratic function of z , the problem is called *linear quadratic*. Of course, $\|z\|^2 = x^\top C^\top Cx + 2u^\top D^\top Cx + u^\top D^\top Du$, so the integrand can also be considered as a quadratic function of (x, u) . The convergence of the integral in (3) is of course a point of concern. Therefore, one often considers the corresponding *finite-horizon problem* in a preliminary investigation. In this problem, a final time T is given and one wants to minimize the integral

$$J(x_0, u, T) := \int_0^T \|z(t)\|^2 dt. \quad (4)$$

In contrast to this, the first problem above is sometimes called the *infinite horizon problem*. An important issue is also the *convergence of the state*. Obviously, convergence of the integral does not always imply the convergence to zero of the state. Therefore, distinction is made between the problem with zero and with free endpoint. Problem 1 as stated is referred to as the *problem with free endpoint*. If one restricts the inputs u in the problem to those for which the resulting state trajectory tends to zero, one speaks about the *problem with zero endpoint*. Specifically:

Problem 2 In the situation of Problem 1, determine for every initial state x_0 an input $u \in \mathbf{U}$ such that $x_u(t, x_0) \rightarrow 0$ ($t \rightarrow \infty$) and such that under this condition, $J(x_0, u)$ is minimized.

In the literature various special cases of these problems have been considered, and names have

been associated to these special cases. In particular, Problems 1 and 2 are called *regular* if the matrix D is injective, equivalently, $D^\top D > 0$. If, in addition, $C^\top D = 0$ and $D^\top D = I$, then the problems are said to be in *standard form*. In the standard case, the integrand in the cost functional reduces to $\|z\|^2 = x^\top C^\top Cx + u^\top u$. We often write $Q = C^\top C$. The standard case is a special case, which is not essentially simpler than the general regular problem, but which gives rise to simpler formulas. The general regular problem can be reduced to the standard case by means of a suitable feedback transformation.

The Finite-Horizon Problem

The finite-horizon problem in standard form is formulated as follows:

Problem 3 Given the system $\dot{x}(t) = Ax(t) + Bu(t)$, a final time $T > 0$, and symmetric matrices N and Q such that $N \geq 0$ and $Q \geq 0$, determine for every initial state x_0 a piecewise continuous input function $u : [0, T] \rightarrow \mathcal{U}$ such that the integral

$$J(x_0, u, T) := \int_0^T x(t)^\top Qx(t) + u(t)^\top u(t) dt + x(T)^\top Nx(T) \quad (5)$$

is minimized.

In this problem, we have introduced a *weight on the final state*, using the matrix N . This generalization of the problem does not give rise to additional complications.

A key ingredient in solving this finite-horizon problem is the *Riccati differential equation* associated with the problem:

$$\begin{aligned} \dot{P}(t) &= A^\top P(t) + P(t)A - P(t)BB^\top P(t) + Q, \\ P(0) &= N. \end{aligned} \quad (6)$$

This is a quadratic differential equation on the interval $[0, \infty]$ in terms of the matrices A , B , and Q , and with initial condition given by the weight matrix N on the final state. The unknown in the differential equation is the matrix valued

function $P(t)$. The following theorem solves the finite-horizon problem. It states that the Riccati differential equation with initial condition (6) has a unique solution on $[0, \infty)$, that the optimal value of the cost functional is determined by the value of this solution at time T , and that there exists a unique optimal input that is generated by a time-varying state feedback control law:

Theorem 1 *Consider Problem 3. The following properties hold:*

1. *The Riccati differential equation with initial value (6) has a unique solution $P(t)$ on $[0, \infty)$. This solution is symmetric and positive semidefinite for all $t \geq 0$.*
2. *For each x_0 there is exactly one optimal input function, i.e., a piecewise continuous function u^* on $[0, T]$ such that $J(x_0, u^*, T) = J^*(x_0, T) := \inf\{J(x_0, u, T) \mid u \in \mathbf{U}\}$. This optimal input function u^* is generated by the time-varying feedback control law*

$$u(t) = -B^\top P(T-t)x(t) \quad (0 \leq t \leq T). \quad (7)$$

3. *For each x_0 , the minimal value of the cost functional equals*

$$J^*(x_0, T) = x_0^\top P(T)x_0.$$

4. *If $N = 0$, then the function $t \mapsto P(t)$ is an increasing function in the sense that $P(t) - P(s)$ is positive semidefinite for $t \geq s$.*

The Infinite-Horizon Problem with Free Endpoint

We consider the situation as described in Theorem 1 with $N = 0$. An obvious conjecture is that $x_0^\top P(T)x_0$ converges to the minimal cost of the infinite-horizon problem as $T \rightarrow \infty$. The convergence of $x_0^\top P(T)x_0$ for all x_0 is equivalent to the convergence of the matrix $P(T)$ for $T \rightarrow \infty$ to some matrix P^- . Such a convergence does not always take place. In order to achieve convergence, we make the following assumption: for every x_0 , there exists an input u for which the integral

$$J(x_0, u) := \int_0^\infty x(t)^\top Qx(t) + u(t)^\top u(t) dt \quad (8)$$

converges, i.e., for which the cost $J(x_0, u)$ is finite. Obviously, for the problem to make sense for all x_0 , this condition is necessary. It is easily seen that the stabilizability of (A, B) is a sufficient condition for the above assumption to hold (not necessary, take, e.g., $Q = 0$). Take an arbitrary initial state x_0 and assume that $\bar{u}$ is a function such that the integral (8) is finite. We have for every $T > 0$ that

$$x_0^\top P(T)x_0 \leq J(x_0, \bar{u}, T) \leq J(x_0, \bar{u}),$$

which implies that for every x_0 , the expression $x_0^\top P(T)x_0$ is bounded. This implies that $P(T)$ is bounded. Since $P(T)$ is increasing with respect to T , it follows that $P^- := \lim_{T \rightarrow \infty} P(T)$ exists. Since P satisfies the differential equation (6), it follows that also $\dot{P}(t)$ has a limit as $t \rightarrow \infty$. It is easily seen that this latter limit must be zero. Hence, $P = P^-$ satisfies the following equation:

$$A^\top P + PA - PBB^\top P + Q = 0. \quad (9)$$

This is called the *algebraic Riccati equation* (ARE). The solutions of this equation are exactly the constant solutions of the Riccati differential equation. The previous consideration shows that the ARE has a positive semidefinite solution P^- . The solution is not necessarily unique, not even with the extra condition that $P \geq 0$. However, P^- turns out to be the *smallest* real symmetric positive semidefinite solution of the ARE.

The following theorem now establishes a complete solution to the regular standard form version of Problem 1:

Theorem 2 *Consider the system $\dot{x}(t) = Ax(t) + Bu(t)$ together with the cost functional*

$$J(x_0, u) := \int_0^\infty x(t)^\top Qx(t) + u(t)^\top u(t) dt,$$

with $Q \geq 0$. Factorize $Q = C^\top C$. Then, the following statements are equivalent:

1. For every $x_0 \in X$, there exists $u \in \mathbf{U}$ such that $J(x_0, u) < \infty$.
2. The ARE (9) has a real symmetric positive semidefinite solution P .

Assume that one of the above conditions holds. Then, there exists a smallest real symmetric positive semidefinite solution of the ARE, i.e., there exists a real symmetric solution $P^- \geq 0$ such that for every real symmetric solution $P \geq 0$, we have $P^- \leq P$. For every x_0 , we have

$$J^*(x_0) := \inf\{J(x_0, u) \mid u \in \mathbf{U}\} = x_0^\top P^- x_0.$$

Furthermore, for every x_0 , there is exactly one optimal input function, i.e., a function $u^* \in \mathbf{U}$ such that $J(x_0, u^*) = J^*(x_0)$. This optimal input is generated by the time-invariant feedback law

$$u(t) = -B^\top P^- x(t).$$

The Infinite-Horizon Problem with Zero Endpoint

In addition to the free endpoint problem, we consider the version of the linear quadratic problem with zero endpoint. In this case the aim is to minimize for every x_0 the cost functional over all inputs u such that $x_u(t, x_0) \rightarrow 0$ ($t \rightarrow \infty$). For each x_0 such u exists if and only if the pair (A, B) is stabilizable. A solution to the regular standard form version of Problem 2 is stated next:

Theorem 3 Consider the system $\dot{x}(t) = Ax(t) + Bu(t)$ together with the cost functional

$$J(x_0, u) := \int_0^\infty x(t)^\top Q x(t) + u(t)^\top u(t) dt,$$

with $Q \geq 0$. Assume that (A, B) is stabilizable. Then:

1. There exists a largest real symmetric solution of the ARE, i.e., there exists a real symmetric solution P^+ such that for every real symmetric solution P , we have $P \leq P^+$. P^+ is positive semidefinite.

2. For every initial state x_0 , we have

$$J_0^*(x_0) = x_0^\top P^+ x_0.$$

3. For every initial state x_0 , there exists an optimal input function, i.e., a function $u^* \in \mathbf{U}$ with $x(\infty) = 0$ such that $J(x_0, u^*) = J_0^*(x_0)$ if and only if every eigenvalue of A on the imaginary axis is (Q, A) observable, i.e., $\text{rank} \begin{pmatrix} A - \lambda I \\ Q \end{pmatrix} = n$ for all $\lambda \in \sigma(A)$ with $\text{Re}(\lambda) = 0$.

Under this assumption we have:

4. For every initial state x_0 , there is exactly one optimal input function u^* . This optimal input function is generated by the time-invariant feedback law

$$u(t) = -B^\top P^+ x(t).$$

5. The optimal closed-loop system $\dot{x}(t) = (A - BB^\top P^+)x(t)$ is stable. In fact, P^+ is the unique real symmetric solution of the ARE for which $\sigma(A - BB^\top P^+) \subset \mathbb{C}^-$.

Summary and Future Directions

Linear quadratic optimal control deals with finding an input function that minimizes a quadratic cost functional for a given linear system. The cost functional is the integral of a quadratic form in the input and state variable of the system. If the integral is taken over a finite time interval the problem is called a finite-horizon problem, and the optimal cost and optimal state feedback gain can be expressed in terms of the solution of an associated Riccati differential equation. If we integrate over an infinite time interval, the problem is called an infinite-horizon problem. The optimal cost and optimal feedback gain for the free endpoint problem can be found in terms of the smallest nonnegative real symmetric solution of the associated algebraic Riccati equation. For the zero endpoint problem, these are given in

terms of the largest real symmetric solution of the algebraic Riccati equation.

Recommended Reading

The linear quadratic regulator problem and the Riccati equation were introduced by R.E. Kalman in the early 1960s (see Kalman (1960)). Extensive treatments of the problem can be found in the textbooks Brockett (1969), Kwakernaak and Sivan (1972), and Anderson and Moore (1971). For a detailed study of the Riccati differential equation and the algebraic Riccati equation, we refer to Wonham (1968). Extensions of the linear quadratic regulator problem to linear quadratic optimization problems, where the integrand of the cost functional is a possibly indefinite quadratic function of the state and input variable, were studied in the classical paper of Willems (1971). A further reference for the geometric classification of all real symmetric solutions of the algebraic Riccati equation is Coppel (1974). For the question what level of system performance can be obtained if, in the cost functional, the weighting matrix of the control input is singular or nearly singular leading to singular and nearly singular linear quadratic optimal control problems and “cheap control” problems, we refer to Kwakernaak and Sivan (1972). An early reference for a discussion on the singular problem is the work of Clements and Anderson (1978). More details can be found in Willems (1971) and Schumacher (1983). In singular problems, in general one allows for distributions as inputs. This approach was worked out in detail in Hautus and Silverman (1983) and Willems et al. (1986). For a more

recent reference, including an extensive list of references, we refer to the textbook of Trentelman et al. (2001).

Linear Quadratic Zero-Sum Two-Person Differential Games

Pierre Bernhard

INRIA-Sophia Antipolis-Méditerranée, Sophia Antipolis, France

Abstract

As in optimal control theory, linear quadratic (LQ) differential games (DG) can be solved, even in high dimension, via a Riccati equation.

However, contrary to the control case, existence of the solution of the Riccati equation is not necessary for the existence of a closed-loop saddle point. One may “survive” a particular, nongeneric, type of conjugate point. An important application of LQDGs is the so-called H_∞ -optimal control, appearing in the theory of robust control.

Perfect State Measurement

Linear quadratic differential games are a special case of differential games (DG). See the article ► [Pursuit-Evasion Games and Zero-Sum Two-Person Differential Games](#). They were first investigated by Ho et al. (1965), in the context of a linearized pursuit-evasion game. This subsection is based upon Bernhard (1979, 1980). A linear quadratic DG is defined as

$$\dot{x} = Ax + Bu + Dv, \quad x(t_0) = x_0,$$

with $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, $v \in \mathbb{R}^\ell$, $u(\cdot) \in L^2([0, T], \mathbb{R}^m)$, $v(\cdot) \in L^2([0, T], \mathbb{R}^\ell)$. Final time T is given, there is no terminal constraint, and using the notation $x^T K x = \|x\|_K^2$,

$$J(t_0, x_0; u(\cdot), v(\cdot)) = \|x(T)\|_K^2 + \int_{t_0}^T (x^t u^t v^t)$$

$$\begin{pmatrix} Q & S_1 & S_2 \\ S_1^t & R & 0 \\ S_2^t & 0 & -\Gamma \end{pmatrix} \begin{pmatrix} x \\ u \\ v \end{pmatrix} dt.$$

The matrices of appropriate dimensions, A , B , D , Q , S_i , R , and Γ , may all be measurable functions of time. R and Γ must be positive definite with inverses bounded away from zero. To get the most complete results available, we assume also that K and Q are nonnegative definite, although this is only necessary for some of the following results. Detailed results without that assumption were

obtained by Zhang (2005) and Delfour (2005). We chose to set the cross term in uv in the criterion null; this is to simplify the results and is not necessary. This problem satisfies Isaacs' condition (see article DG) even with nonzero such cross terms.

Using the change of control variables

$$u = \tilde{u} - R^{-1} S_1^t x, \quad v = \tilde{v} + \Gamma^{-1} S_2^t x,$$

yields a DG with the same structure, with modified matrices A and Q , but without the cross terms in xu and xv . (This extends to the case with nonzero cross terms in uv .) Thus, without loss of generality, we will proceed with $(S_1 \ S_2) = (0 \ 0)$.

The existence of open-loop and closed-loop solutions to that game is ruled by two Riccati equations for symmetric matrices P and P^* , respectively, and by a pair of canonical equations that we shall see later:

$$\begin{aligned} \dot{P} + PA + A^t P - PBR^{-1}B^t P + PD\Gamma^{-1}D^t P \\ + Q = 0, \quad P(T) = K, \end{aligned} \quad (1)$$

$$\begin{aligned} \dot{P}^* + P^*A + A^t P^* + P^*D\Gamma^{-1}D^t P^* + Q = 0, \\ P^*(T) = K. \end{aligned} \quad (2)$$

When both Riccati equations have a solution over $[t, T]$, it holds that in the partial ordering of definiteness,

$$0 \leq P(t) \leq P^*(t).$$

When the saddle point exists, it is represented by the state feedback strategies

$$u = \varphi^*(t, x) = -R^{-1}B^t P(t)x,$$

$$v = \psi^*(t, x) = \Gamma^{-1}D^t P(t)x. \quad (3)$$

The control functions generated by this pair of feedbacks will be noted $\hat{u}(\cdot)$ and $\hat{v}(\cdot)$.

Theorem 1

- A sufficient condition for the existence of a closed-loop saddle point, then given by

- (φ^*, ψ^*) in (3), is that Eq. (1) has a solution $P(t)$ defined over $[t_0, T]$.
- A necessary and sufficient condition for the existence of an open-loop saddle point is that Eq. (2) has a solution over $[t_0, T]$ (and then so does (1)). In that case, the pairs $(\hat{u}(\cdot), \hat{v}(\cdot))$, $(\hat{u}(\cdot), \psi^*)$, and (φ^*, ψ^*) are saddle points.
 - A necessary and sufficient condition for $(\varphi^*, \hat{v}(\cdot))$ to be a saddle point is that Eq. (1) has a solution over $[t_0, T]$.
 - In all cases where a saddle point exists, the Value function is $V(t, x) = \|x\|_{P(t)}^2$.

However, Eq. (1) may fail to have a solution and a closed-loop saddle point still exists. The precise necessary condition is as follows: let $X(\cdot)$ and $Y(\cdot)$ be two square matrix function solutions of the canonical equations

$$\begin{pmatrix} \dot{X} \\ \dot{Y} \end{pmatrix} = \begin{pmatrix} A & -BR^{-1}B^t + D\Gamma^{-1}D^t \\ -Q & -A^t \end{pmatrix} \begin{pmatrix} X \\ Y \end{pmatrix},$$

$$\begin{pmatrix} X(T) \\ Y(T) \end{pmatrix} = \begin{pmatrix} I \\ K \end{pmatrix}.$$

The matrix $P(t)$ exists for $t \in [t_0, T]$ if and only if $X(t)$ is invertible over that range, and then, $P(t) = Y(t)X^{-1}(t)$. Assume that the rank of $X(t)$ is piecewise constant, and let $X^\dagger(t)$ denote the pseudo-inverse of $X(t)$ and $\mathcal{R}(X(t))$ its range.

Theorem 2 *A necessary and sufficient condition for a closed-loop saddle point to exist, which is then given by (3) with $P(t) = Y(t)X^\dagger(t)$, is that*

1. $x_0 \in \mathcal{R}(X(t_0))$.
2. For almost all $t \in [t_0, T]$, $\mathcal{R}(D(t)) \subset \mathcal{R}(X(t))$.
3. $\forall t \in [t_0, T]$, $Y(t)X^\dagger(t) \geq 0$.

In a case where $X(t)$ is only singular at an isolated instant t^* (then conditions 1 and 2 above are automatically satisfied), called a *conjugate point* but where YX^{-1} remains positive definite on both sides of it, the conjugate point is called *even*. The feedback gain $F = -R^{-1}B^tP$

diverges upon reaching t^* , but on a trajectory generated by this feedback, the control $u(t) = F(t)x(t)$ remains finite. (See an example in Bernhard 1979.)

If $T = \infty$, with all system and payoff matrices constant and $Q > 0$, Mageirou (1976) has shown that if the algebraic Riccati equation obtained by setting $\dot{P} = 0$ in (1) admits a positive definite solution P , the game has a Value $\|x\|_P^2$, but (3) may not be a saddle point. (ψ^* may not be an equilibrium strategy.)

H_∞ -Optimal Control

This subsection is entirely based upon Başar and Bernhard (1995). It deals with imperfect state measurement, using Bernhard's nonlinear *minimax certainty equivalence principle* (Bernhard and Rapaport 1996).

Several problems of robust control may be brought to the following one: a linear, time-invariant system with two inputs (control input $u \in \mathbb{R}^m$ and disturbance input $w \in \mathbb{R}^\ell$) and two outputs (measured output $y \in \mathbb{R}^p$ and controlled output $z \in \mathbb{R}^q$) is given. One wishes to control the system with a nonanticipative controller $u(\cdot) = \phi(y(\cdot))$ in order to minimize the induced linear operator norm between spaces of square-integrable functions, of the resulting operator $w(\cdot) \mapsto z(\cdot)$.

It turns out that the problem which has a tractable solution is a kind of dual one: given a positive number γ , is it possible to make this norm no larger than γ ? The answer to this question is yes if and only if

$$\inf_{\phi \in \Phi} \sup_{w(\cdot) \in L^2} \int_{-\infty}^{\infty} (\|z(t)\|^2 - \gamma^2 \|w(t)\|^2) dt \leq 0.$$

We shall extend somewhat this classical problem by allowing either a time variable system, with a finite horizon T , or a time-invariant system with an infinite horizon.

The dynamical system is

$$\dot{x} = Ax + Bu + Dw, \quad (4)$$

$$y = Cx + Ew, \quad (5)$$

$$z = Hx + Gu. \quad (6)$$

We let

$$\begin{pmatrix} D \\ E \end{pmatrix} (D^t \ E^t) = \begin{pmatrix} M \ L \\ L^t \ N \end{pmatrix},$$

$$\begin{pmatrix} H^t \\ G^t \end{pmatrix} (H \ G) = \begin{pmatrix} Q \ S \\ S^t \ R \end{pmatrix},$$

and we assume that E is onto, $\Leftrightarrow N > 0$, and G is one-to-one $\Leftrightarrow R > 0$.

Finite Horizon

In this part, we consider a time-varying system, with all matrix functions measurable. Since the state is not known exactly, we assume that the initial state is not known either. The issue is therefore to decide whether the criterion

$$J_\gamma = \|x(T)\|_K^2 + \int_{t_0}^T (\|z(t)\|^2 - \gamma^2 \|w(t)\|^2) dt - \gamma^2 \|x_0\|_{\Sigma_0}^2 \quad (7)$$

may be kept finite and with which strategy. Let

$$\gamma^* = \inf\{\gamma \mid \inf_{\phi \in \Phi} \sup_{x_0 \in \mathbb{R}^n, w(\cdot) \in L^2} J_\gamma < \infty\}.$$

Theorem 3 $\gamma \leq \gamma^*$ if and only if the following three conditions are satisfied:

1. The following Riccati equation has a solution over $[t_0, T]$:

$$\begin{aligned} -\dot{P} = & PA + A^t P - (PB + S)R^{-1}(B^t P + S^t) \\ & + \gamma^{-2} PMP + Q, \quad P(T) = K. \end{aligned} \quad (8)$$

2. The following Riccati equation has a solution over $[t_0, T]$:

$$\begin{aligned} \dot{\Sigma} = & A\Sigma + \Sigma A^t - (\Sigma C^t + L)N^{-1}(C\Sigma + L^t) \\ & + \gamma^{-2} \Sigma Q \Sigma + M, \quad \Sigma(t_0) = \Sigma_0. \end{aligned} \quad (9)$$

3. The following spectral radius condition is satisfied:

$$\forall t \in [t_0, T], \quad \rho(\Sigma(t)P(t)) < \gamma^2. \quad (10)$$

In that case, the optimal controller ensuring $\inf_{\phi} \sup_{x_0, w} J_\gamma$ is given by a “worst case state” $\hat{x}(\cdot)$ satisfying $\hat{x}(0) = 0$ and

$$\begin{aligned} \dot{\hat{x}} = & [A - BR^{-1}(B^t P + S^t) + \gamma^{-2} D(D^t P + L^t)] \\ & \hat{x} + (I - \gamma^{-2} \Sigma P)^{-1} (\Sigma C^t + L)(y - C\hat{x}), \end{aligned} \quad (11)$$

and the certainty equivalent controller

$$\phi^*(y(\cdot))(t) = -R^{-1}(B^t P + S^t)\hat{x}(t). \quad (12)$$

Infinite Horizon

The infinite horizon case is the traditional H_∞ -optimal control problem reformulated in a state space setting. We let all matrices defining the system be constant. We take the integral in (7) from $-\infty$ to $+\infty$, with no initial or terminal term of course. We add the hypothesis that the pairs (A, B) and (A, D) are stabilizable and the pairs (C, A) and (H, A) detectable. Then, the theorem is as follows:

Theorem 4 $\gamma \leq \gamma^*$ if and only if the following conditions are satisfied: The algebraic Riccati equations obtained by placing $\dot{P} = 0$ and $\dot{\Sigma} = 0$ in (8) and (9) have positive definite solutions, which satisfy the spectral radius condition (10). The optimal controller is given by Eqs. (11) and (12), where P and Σ are the minimal positive definite solutions of the algebraic Riccati equations, which can be obtained as the limit of the solutions of the differential equations as $t \rightarrow -\infty$ for P and $t \rightarrow \infty$ for Σ .

Conclusion

The similarity of the H_∞ -optimal control theory with the LQG, stochastic, theory is in many respects striking, as is the duality observation control. Yet, the “observer” of H_∞ -optimal control does *not* arise from some estimation theory but from the analysis of a “worst case.” The best explanation might be in the duality of

the ordinary, or $(+, \times)$, algebra with the idempotent $(\max, +)$ algebra (see Bernhard 1996). The complete theory of H_∞ -optimal control in that perspective has yet to be written.

Abstract

Feedback is a fundamental mechanism in nature and central in the control of systems. The state of a system contains important information about the system; hence feeding back the state is a powerful control policy. To illustrate the effect of feedback in linear systems, continuous- and discrete-time state-variable descriptions are used: these allow the resulting closed-loop descriptions to be explicitly written and the effect of feedback on the eigenvalues of the closed-loop system to be studied. The eigenvalue assignment problem is also discussed.

Keywords

Linear systems · Feedback · Stabilization

Introduction

Feedback is a fundamental mechanism arising in nature. Feedback is also common in engineered systems and is essential in the automatic control of dynamic processes with uncertainties in their

model descriptions and in their interactions with the environment. When feedback is used, the values of the system variables are sensed, fed back, and used to control the system. That is, a control law decision process is based not only on predictions about the system behavior derived from a process model (as in open-loop control), but also on information about the actual behavior (closed-loop feedback control). If not all state variables are sensed, one could resort to a control architecture which relies on available measurements, such as the output of the system, and on an estimation mechanism, which generates an asymptotically converging estimate of the state to be used for feedback.

Linear Continuous-Time Systems

Consider, to begin with, time-invariant systems described by the state-variable description

$$\dot{x} = Ax + Bu, \quad y = Cx + Du, \quad (1)$$

in which $x(t) \in \mathbb{R}^n$ is the state, $u(t) \in \mathbb{R}^m$ is the input, $y(t) \in \mathbb{R}^p$ is the output, and $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, and $D \in \mathbb{R}^{p \times m}$ are constant matrices. In this case the linear state feedback (lsf) control law is selected as

$$u(t) = Fx(t) + r(t), \quad (2)$$

where $F \in \mathbb{R}^{m \times n}$ is the constant lsf gain matrix and $r(t) \in \mathbb{R}^m$ is a new external input.

Substituting (2) into (1) yields the closed-loop state variable description, namely

$$\begin{aligned} \dot{x} &= (A + BF)x + Br, \\ y &= (C + DF)x + Dr. \end{aligned} \quad (3)$$

Appropriately selecting F , primarily to modify $A + BF$, one affects and improves the behavior of the system.

A number of comments are in order.

- Feeding back the information from the state x of the system is expected to be, and it is,

an effective way to alter the system behavior. This is because knowledge of the (initial) state and the input, in the absence of measurement noise and disturbances, uniquely determines the system's future behavior and, intuitively, using the state information should be a good way to control the system.

- In a state feedback control law the input u can be any function of the state, that is, $u = f(x, r)$, not necessarily linear with constant gain F as in (2). Typically, given (1), (2) is selected as the lsf primarily because the resulting closed-loop description (3) is also a linear time-invariant system. However, depending on the application needs, the state feedback control law can be more complex than (2).
- Although the equations (3) that describe the closed-loop behavior are different from equations (1), this does not imply that the system parameters have changed. The way feedback control acts is not by changing the system parameters A , B , C , and D , but by changing u so that the closed-loop system behaves as if the parameters were changed. When one applies say a step via $r(t)$ in the closed-loop system, then u in (2) is modified appropriately so the system behaves in a desired way.
- It is possible to implement u in (2) as an open-loop control law, namely

$$\begin{aligned} \hat{u} &= F[sI - (A + BF)]^{-1}x(0) \\ &\quad + [I - F(sI - A)^{-1}B]^{-1}\hat{r}, \end{aligned} \quad (4)$$

where the Laplace transforms $\hat{u} = \hat{u}(s)$ and $\hat{r} = \hat{r}(s)$ have been used for notational convenience. Equation (4) produces exactly the same input as equation (2), but it has the serious disadvantage that it is based exclusively on prior knowledge on the system (notably $x(0)$). As a result when there are uncertainties (and there always are), the open-loop control law (4) may fail, while the closed-loop control law (2) succeeds.

Analogous definitions exist for continuous-time, time-varying, systems described by the equations

$$\dot{x} = A(t)x + B(t)u, \quad y = C(t)x + D(t)u. \quad (5)$$

In this framework the lsf control law is given by

$$u = F(t)x + r, \quad (6)$$

and the resulting closed-loop system is

$$\begin{aligned} \dot{x} &= [A(t) + B(t)F(t)]x + B(t)r, \\ y &= [C(t) + D(t)F(t)]x + D(t)r. \end{aligned} \quad (7)$$

Linear Discrete-Time Systems

For the discrete-time, time-invariant, case the system description is

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k), \\ y(k) &= Cx(k) + Du(k), \end{aligned} \quad (8)$$

the lsf control law is defined as

$$u(k) = Fx(k) + r(k), \quad (9)$$

and the closed-loop system is described by

$$\begin{aligned} x(k+1) &= (A + BF)x(k) + Br(k), \\ y(k) &= (C + DF)x(k) + Dr(k). \end{aligned} \quad (10)$$

Similarly, for the discrete-time, time-varying, case

$$\begin{aligned} x(k+1) &= A(k)x(k) + B(k)u(k), \\ y(k) &= C(k)x(k) + D(k)u(k), \end{aligned} \quad (11)$$

the lsf control law is defined as

$$u(k) = F(k)x(k) + r(k), \quad (12)$$

and the resulting closed-loop system is

$$\begin{aligned} x(k+1) &= [A(k) + B(k)F(k)]x(k) \\ &\quad + B(k)r(k), \\ y(k) &= [C(k) + D(k)F(k)]x(k) \\ &\quad + D(k)r(k). \end{aligned} \quad (13)$$

Selecting the Gain F

We select F (or $F(t)$) so that the closed-loop system has certain desirable properties. Stability is of course of major importance, although several control requirements can be addressed using lsf including, for example, tracking and regulation, diagonal decoupling, and disturbance rejection. In what follows we shall focus on stability. Stability can be achieved under appropriate controllability assumptions. In the time-varying case, one way to determine such a stabilizing $F(t)$ (or $F(k)$) is to use results from the optimal Linear Quadratic Regulator (LQR) theory which yields the “best” $F(t)$ in some sense.

In the time-invariant case, stabilization is equivalent to the problem of assigning the n eigenvalues of $(A + BF)$ in the stable region of the complex plane. If $\lambda_i, i = 1, \dots, n$, are the eigenvalues of $A + BF$, then F should be chosen so that, for all $i = 1, \dots, n$, the real part of λ_i is negative, that is, $Re(\lambda_i) < 0$ in the continuous time case, and the magnitude of λ_i is smaller than one, that is, $|\lambda_i| < 1$, in the discrete time case. Eigenvalue assignment is therefore an important objective which is discussed hereafter.

Eigenvalue Assignment Problem

For continuous-time and discrete-time, time-invariant, systems the eigenvalue assignment problem can be posed as follows. Given matrices $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$, find $F \in \mathbb{R}^{m \times n}$ such that the eigenvalues of $A + BF$ are assigned to arbitrary, complex conjugate, locations. Note that the characteristic polynomial of $A + BF$, namely, $\det(sI - (A + BF))$, has real coefficients, which implies that any complex eigenvalue is one of a pair of complex conjugate eigenvalues.

For single-input systems, that is, for systems with $m = 1$, the eigenvalue assignment problem has a simple solution, as illustrated in the following statement.

Proposition 1 Consider system (1) or (8). Let $m = 1$. Assume that

$$\text{rank } R = n,$$

where

$$R = [B, AB, \dots, A^{n-1}B],$$

that is, the system is reachable. Let $p(s)$ be a monic polynomial of degree n . Then there is a (unique) lsf gain matrix F such that the characteristic polynomial of $A + BF$ is equal to $p(s)$. Such an lsf gain matrix F is given by

$$F = -[0 \dots 0 \ 1] R^{-1} p(A). \quad (14)$$

Proposition 1 provides a constructive way to assign the characteristic polynomial, hence the eigenvalues, of the matrix $A + BF$. Note that, for low-order systems, i.e., if $n = 2$ or $n = 3$, it may be convenient to compute directly the characteristic polynomial of $A + BF$ and then compute F using the principle of identity of polynomials, i.e., F should be such that the coefficients of the polynomials $\det(sI - (A + BF))$ and $p(s)$ coincide. Equation (14) is known as Ackermann's formula.

The result summarized in Proposition 1 can be extended to multi-input systems.

Proposition 2 Consider system (1) or (8). Suppose

$$\text{rank } R = n,$$

that is the system is reachable. Let $p(s)$ be a monic polynomial of degree n . Then there is a lsf gain matrix F such that the characteristic polynomial of $A + BF$ is equal to $p(s)$.

Note that in the case $m > 1$ the lsf gain matrix F assigning the characteristic polynomial of the matrix $A + BF$ is not unique. To compute one such a lsf gain matrix one may exploit the following fact.

Lemma 1 (Heymann) Consider system (1) or (8). Suppose

$$\text{rank } R = n,$$

that is, the system is reachable. Let b_i be a nonzero column of the matrix B . Then there is a matrix G such that the single-input system (for convenience we write the system in

continuous time, but the same conclusions hold in the discrete-time case)

$$\dot{x} = (A + BG)x + b_i v, \quad (15)$$

is reachable.

Exploiting Lemma 1 it is possible to design a matrix F such that the characteristic polynomial of $A + BF$ equals some monic polynomial $p(s)$ of degree n in two steps. First we compute a matrix G such that the system (15) is reachable, and then we use Ackermann's formula to compute a lsf gain matrix F such that the characteristic polynomial of

$$A + BG + b_i F$$

is $p(s)$.

Transfer Functions

If $H_F(s)$ is the transfer function matrix of the closed-loop system (3), it is of interest to find its relation to the open-loop transfer function $H(s)$ of (1). It can be shown that

$$\begin{aligned} H_F(s) &= H(s)[I - F(sI - A)^{-1}B]^{-1} \\ &= H(s)[F(sI - (A + BF))^{-1}B + I]. \end{aligned}$$

In the single-input, single-output, case it can be readily shown that the lsf control law (2) only changes the coefficients of the denominator polynomial in the transfer function (this result is also true in the multi-input, multi-output case). Therefore if any of the (stable) zeros of $H(s)$ needs to be changed the only way to accomplish this via lsf is by pole-zero cancellation (assigning closed-loop poles at the open-loop zero locations; in the multi-input, multi-output case, closed-loop eigenvalue directions also need to be assigned for cancellations to take place).

Observer-Based Dynamic Controllers

When the state x is not available for feedback, an asymptotic estimator (a Luenberger observer) is

typically used to estimate the state. The estimate $\hat{x}$ of the state, instead of the actual x , is then used in (2) to control the system, in what is known as the *certainty equivalence* architecture.

Summary and Future Directions

The notion of state feedback for linear systems, possibly time-varying, has been discussed. It has been shown that state feedback modifies the closed-loop behavior. The related problem of eigenvalue assignment has been discussed and its connection with the reachability properties of the system has been highlighted. The class of feedback laws considered is the simplest possible one: if additional constraints on the input signal, or on the closed-loop performance, are imposed, then one has to resort to nonlinear state feedback or to dynamic state feedback. This is the case, for example, if the input signal is bounded in amplitude and/or rate or if one has to solve the so-called noninteracting control problem with stability, that is, the problem of designing a feedback law yielding asymptotic stability and such that the closed-loop system is composed of m decoupled subsystems.

Linear Systems: Continuous-Time Impulse Response Descriptions

Panos J. Antsaklis

Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

An important input–output description of a linear continuous-time system is its impulse response, which is the response $h(t, \tau)$ to an impulse applied at time τ . In time-invariant systems that are also causal and at rest at time zero, the impulse response is $h(t, 0)$ and its Laplace transform is the transfer function of the system. Expressions for $h(t, \tau)$ when the system is described by state-variable equations are also derived.

Keywords

Continuous-time · Impulse response descriptions · Linear systems · Time-invariant · Time-varying · Transfer function descriptions

Introduction

Consider linear continuous-time dynamical systems, the input–output behavior of which can be described by an integral representation of the form

$$y(t) = \int_{-\infty}^{+\infty} H(t, \tau) u(\tau) d\tau \quad (1)$$

where $t, \tau \in \mathbb{R}$, the output is $y(t) \in \mathbb{R}^p$, the input is $u(t) \in \mathbb{R}^m$, and $H : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}^{p \times m}$ is assumed to be integrable. For instance, any system in state-variable form

$$\begin{aligned}\dot{x} &= A(t)x + B(t)u \\ y &= C(t)x + D(t)u\end{aligned}\quad (2)$$

or

$$\begin{aligned}\dot{x} &= Ax + Bu \\ y &= Cx + Du\end{aligned}\quad (3)$$

also has a representation of the form (1) as we shall see below.

Note that it is assumed that at $\tau = -\infty$, the system is at rest. $H(t, \tau)$ is the *impulse response matrix* of the system (1). To explain, consider first a single-input single-output system:

$$y(t) = \int_{-\infty}^{+\infty} h(t, \tau)u(\tau)d\tau, \quad (4)$$

and recall that if $\delta(\hat{t} - \tau)$ denotes an impulse (delta or Dirac) function applied at time $\tau = \hat{t}$, then for a function $f(t)$,

$$f(\hat{t}) = \int_{-\infty}^{+\infty} f(\tau)\delta(\hat{t} - \tau)d\tau. \quad (5)$$

If now in (4) $u(\tau) = \delta(\hat{t} - \tau)$, that is, an impulse input is applied at $\tau = \hat{t}$, then the output $y_I(t)$ is

$$y_I(t) = h(t, \hat{t}),$$

i.e., $h(t, \hat{t})$ is the output at time t when an impulse is applied at the input at time $\hat{t}$. So in (4), $h(t, \tau)$ is the response at time t to an impulse applied at time τ . Clearly if the *impulse response* $h(t, \tau)$ is known, the response to any input $u(t)$ can be derived via (4), and so $h(t, \tau)$ is an input/output description of the system.

Equation (1) is a generalization of (4) for the multi-input, multi-output case. If we let all the components of $u(\tau)$ in (1) be zero except the j th component, then

$$y_i(t) = \int_{-\infty}^{+\infty} h_{ij}(t, \tau)u_j(\tau)d\tau, \quad (6)$$

$h_{ij}(t, \tau)$ denotes the response of the i th component of the output of system (1) at time t due to an impulse applied to the j th component of the input at time τ with all remaining components of the input being zero. $H(t, \tau) = [h_{ij}(t, \tau)]$ is called the *impulse response matrix* of the system.

If it is known that system (1) is causal, then the output will be zero before an input is applied. Therefore,

$$H(t, \tau) = 0, \quad \text{for } t < \tau, \quad (7)$$

and (1) becomes

$$y(t) = \int_{-\infty}^t H(t, \tau)u(\tau)d\tau. \quad (8)$$

Rewrite (8) as

$$\begin{aligned}y(t) &= \int_{-\infty}^{t_0} H(t, \tau)u(\tau)d\tau + \int_{t_0}^t H(t, \tau)u(\tau)d\tau \\ &= y(t_0) + \int_{t_0}^t H(t, \tau)u(\tau)d\tau.\end{aligned}\quad (9)$$

If (1) is at rest at $t = t_0$ (i.e., if $u(t) = 0$ for $t \geq t_0$, then $y(t) = 0$ for $t \geq t_0$), $y(t_0) = 0$ and (9) becomes

$$y(t) = \int_{t_0}^t H(t, \tau)u(\tau)d\tau. \quad (10)$$

If in addition system (1) is time-invariant, then $H(t, \tau) = H(t - \tau, 0)$ (also written as $H(t - \tau)$) since only the elapsed time $(t - \tau)$ from the application of the impulse is important. Then (10) becomes

$$y(t) = \int_0^t H(t - \tau)u(\tau)d\tau, \quad t \geq 0, \quad (11)$$

where we chose $t_0 = 0$ without loss of generality. Equation (11) is the description for causal, time-invariant systems, at rest at $t = 0$.

Equation (11) is a convolution integral and if we take the (one-sided or unilateral) Laplace transform of both sides,

$$\hat{y}(s) = \hat{H}(s)\hat{u}(s), \quad (12)$$

where $\hat{y}(s)$, $\hat{u}(s)$ are the Laplace transforms of $y(t)$, $u(t)$ and $\hat{H}(s)$ is the Laplace transform of the impulse response $H(t)$. $\hat{H}(s)$ is the *transfer function matrix* of the system. Note that the transfer function of a linear, time-invariant system is typically defined as the rational matrix $\hat{H}(s)$ that satisfies (12) for any input and its corresponding output assuming zero initial conditions, which is of course consistent with the above analysis.

Connection to State-Variable Descriptions

When a system is described by the state-variable description (2), then

$$y(t) = \int_{t_0}^t [C(\tau)\Phi(t, \tau)B(\tau) + D(\tau)\delta(t - \tau)]u(\tau)d\tau, \quad (13)$$

where it was assumed that $x(t_0) = 0$, i.e., the system is at rest at t_0 . Here $\Phi(t, \tau)$ is the state transition matrix of the system defined by the Peano-Baker series:

$$\begin{aligned} \Phi(t, t_0) = I &+ \int_{t_0}^t A(\tau_1)d\tau_1 \\ &+ \int_{t_0}^t A(\tau_1) \left[\int_{t_0}^{\tau_1} A(\tau_2)d\tau_2 \right] d\tau_1 + \cdots; \end{aligned}$$

see ► [Linear Systems: Continuous-Time, Time-Varying State Variable Descriptions](#).

Comparing (13) with (10), the impulse response

$$H(t, \tau) = \begin{cases} C(t)\Phi(t, \tau)B(t) + D(t)\delta(t - \tau) & t \geq \tau, \\ 0 & t < \tau. \end{cases} \quad (14)$$

Similarly, when the system is time-invariant and is described by (3),

$$y(t) = \int_{t_0}^t [Ce^{A(t-\tau)}B + D\delta(t - \tau)]u(\tau)d\tau, \quad (15)$$

where $x(t_0) = 0$.

Comparing (15) with (11), the impulse response

$$H(t - \tau) = \begin{cases} Ce^{A(t-\tau)}B + D\delta(t - \tau) & t \geq \tau, \\ 0 & t < \tau, \end{cases} \quad (16)$$

or as it is commonly written (taking the time when the impulse is applied to be zero, $\tau = 0$)

$$H(t) = \begin{cases} Ce^{At}B + D\delta(t) & t \geq 0, \\ 0 & t < 0. \end{cases} \quad (17)$$

Take now the (one-sided or unilateral) Laplace transform of both sides in (17) to obtain

$$\hat{H}(s) = C(sI - A)^{-1}B + D, \quad (18)$$

which is the transfer function matrix in terms of the coefficient matrices in the state-variable description (3). Note that (18) can also be derived directly from (3) by assuming zero initial conditions ($x(0) = 0$) and taking Laplace transform of both sides.

Finally, it is easy to show that equivalent state-variable descriptions give rise to the same impulse responses.

Summary

The continuous-time impulse response is an external, input–output description of linear, continuous-time systems. When the system is time-invariant, the Laplace transform of the impulse response $h(t, 0)$ (which is the output response at time t due to an impulse applied at time zero with initial conditions taken to be zero) is the transfer function of the system – another very common input–output description. The relationships with the state-variable descriptions are shown.

Linear Systems: Continuous-Time, Time-Invariant State Variable Descriptions

Panos J. Antsaklis
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Continuous-time processes that can be modeled by linear differential equations with constant coefficients can also be described in a systematic way in terms of state variable descriptions of the form $\dot{x}(t) = Ax(t) + Bu(t)$, $y(t) = Cx(t) + Du(t)$. The response of such systems due to a given input and a set

of initial conditions is derived and expressed in terms of the variation of constants formula. Equivalence of state variable descriptions is also discussed.

Introduction

Linear, continuous-time systems are of great interest because they model, exactly or approximately, the behavior over time of many practical physical systems of interest. We are particularly interested in systems, the behavior of which is described by linear, ordinary differential equations with constant coefficients.

Such descriptions can always be rewritten as a set of first-order differential equations, typically in the following convenient state variable form:

$$\begin{aligned}\dot{x} &= Ax(t) + Bu(t), & y(t) &= Cx(t) + Du(t); \\ x(0) &= x_0,\end{aligned}\tag{1}$$

where $x(t)$, the state vector, is a column vector of dimension n ($x(t) \in \mathbb{R}^n$) and $\dot{x}(t) = \frac{dx}{dt}$ with the derivative being taken element by element. $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, $D \in \mathbb{R}^{p \times m}$ are matrices with real entries (these are the constant coefficients that make the system time invariant); and $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^p$ are the inputs and outputs of the system. The vector differential equation is the *state equation* and the algebraic equation is the *output equation*.

The advantage of the above state variable description is that for given input $u(t)$ and initial condition $x(0)$, its solution (state and output motions or trajectories) can be conveniently and systematically characterized. This is shown below.

Deriving State Variable Descriptions

Description (1) may be derived directly, by modeling the behavior of a linear, continuous-time, time-invariant system, but more often it is derived either from the linearization of a nonlinear equation around an operating point or a trajectory or from higher-order differential equations that model the system's behavior. The example below illustrates the latter case.

Consider a spring-mass example, where a mass m slides horizontally on a surface with damping coefficient b due to friction and it is attached to a wall by a linear spring of spring constant k . If $y(t)$ denotes the distance of the center of the mass from a position of rest of the spring, by applying Newton's law the following second-order linear ordinary differential equation with constant coefficients is obtained:

$$m\ddot{y}(t) + b\dot{y}(t) + ky(t) = u(t). \quad (2)$$

Here $\dot{y}(t) = \frac{dy(t)}{dt}$. The motion of the mass $y(t)$, $t > 0$ is uniquely determined if the applied force $u(t)$, $t \geq 0$ is known and at $t = 0$ the initial position $y(0) = y_0$ and initial velocity $\dot{y}(0) = y_1$ are given. To obtain a state variable description, introduce the state variables x_1 and x_2 as

$$x_1(t) = y(t), \quad x_2(t) = \dot{y}(t)$$

to obtain the set of first-order differential equations $m\dot{x}_2(t) + bx_2(t) + kx_1(t) = u(t)$ and $\dot{x}(t) = \begin{bmatrix} x_2(t) \\ \frac{1}{m}(-kx_1(t) - bx_2(t) + u(t)) \end{bmatrix}$ which can be rewritten in the form of (1)

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\frac{k}{m} & -\frac{b}{m} \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{m} \end{bmatrix} u(t) \quad (3)$$

and

$$y(t) = \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}$$

with $\begin{bmatrix} x_1(0) \\ x_2(0) \end{bmatrix} = \begin{bmatrix} y_0 \\ y_1 \end{bmatrix}$ as initial conditions. This is of the form (1) where $x(t)$ is a 2-dimensional column vector; A is a 2×2 matrix; B and C are 2-dimensional column and row vectors, respectively; and $x(0) = x_0$.

Notes:

1. It is always possible to obtain a state variable description which is equivalent to a given set of higher-order differential equations
2. The choice of the state variables, here x_1 and x_2 , is not unique. Different choices will lead to different A , B , and C .
3. The number of the state variables is typically equal to the order of the set of the higher-order differential equations and equals the number of initial conditions needed to derive the unique solution; in the above example this number is 2.
4. In time-invariant systems, it can be assumed without loss of generality that the starting time is $t = 0$ and so the initial conditions are taken to be $x(0) = x_0$.

Solving $\dot{x} = A(t)x$; $x(0) = x_0$

Consider the homogeneous equation

$$\dot{x} = A(t)x; \quad x(0) = x_0 \quad (4)$$

where $x(t) = [x_1(t), \dots, x_n(t)]^T$ is the state vector of dimension n and A is an $n \times n$ matrix with entries real numbers (i.e., $A \in \mathbb{R}^{n \times n}$).

Equation (4) is a special case of (1) where there are no inputs and outputs, u and y . The homogeneous vector differential equation (4) will

be solved first, and its solution will be used to find the solution of (1).

Solving (4) is an initial value problem. It can be shown that there always exists a unique solution $\varphi(t)$ such that

$$\dot{\varphi}(t) = A\varphi(t); \quad \varphi(0) = x_0.$$

To find the unique solution, consider first the one-dimensional case, namely,

$$\dot{y}(t) = ay(t); \quad y(0) = y_0$$

the unique solution of which is

$$y(t) = e^{at} y_0, \quad t \geq 0.$$

The scalar exponential e^{at} can be expressed in a series form

$$e^{at} = \sum_{k=0}^{\infty} \frac{t^k}{k!} a^k (= 1 + \frac{1}{1}ta + \frac{1}{2}t^2a^2 + \frac{1}{6}t^3a^3 + \dots)$$

The generalization to the $n \times n$ matrix exponential (A is $n \times n$) is given by

$$e^{At} = \sum_{k=0}^{\infty} \frac{t^k}{k!} A^k \quad (= I_n + At + \frac{1}{2}A^2t^2 + \dots) \quad (5)$$

By analogy, let the solution to (4) be

$$(x(t) =) \varphi(t) = e^{At} x_0 \quad (6)$$

It is a solution since if it is substituted into (4),

$$\begin{aligned} \dot{\varphi}(t) &= [A + At + \frac{1}{2}A^2t^2 + \dots]x_0 \\ &= Ae^{At}x_0 = A\varphi(t) \end{aligned}$$

and $\varphi(0) = e^{A \cdot 0}x_0 = x_0$, that is, it satisfies the equation and the initial condition. Since the solution of (4) is unique, (6) is the unique solution of (4).

The solution (6) can be derived more formally using the Peano-Baker series (see ► [Linear Systems: Continuous-Time, Time-Varying State Variable Descriptions](#)), which in the present time-invariant case becomes the defining series for the matrix exponential (5).

System Response

Based on the solution of the homogeneous equation (4), shown in (6), the solution of the state equation in (1) can be shown to be

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)d\tau. \quad (7)$$

The following properties for the matrix exponential e^{At} can be shown directly from the defining series:

1. $Ae^{At} = e^{At}A$.
2. $(e^{At})^{-1} = e^{-At}$.

Equation (7) which is known as the *variation of constants formula* can be derived as follows:

Consider $\dot{x} = Ax + Bu$ and let $z(t) = e^{-At}x(t)$. Then $x(t) = e^{At}z(t)$ and substituting

$$Ae^{At}z(t) + e^{At}\dot{z}(t) = Ae^{At}z(t) + Bu(t)$$

or $\dot{z}(t) = e^{-At}Bu(t)$ from which

$$z(t) - z(0) = \int_0^t e^{-A\tau}Bu(\tau)d\tau$$

or

$$e^{-At}x(t) - x(0) = \int_0^t e^{-A\tau}Bu(\tau)d\tau$$

or

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)d\tau$$

which is the variation of constants formula (7).

Equation (7) is the sum of two parts, the *state response* (when $u(t) = 0$ and the system is driven only by the initial state conditions) and the *input response* (when $x_0 = 0$ and the system is driven only by the input $u(t)$); this illustrates the linear system principle of superposition.

If the output equation $y(t) = Cx(t) + Du(t)$ is considered, then in view of (7),

$$\begin{aligned}
 y(t) &= Ce^{At}x_0 + \int_0^t Ce^{A(t-\tau)}Bu(\tau)d\tau + Du(t) \\
 &= Ce^{At}x_0 + \int_0^t [Ce^{A(t-\tau)}B \\
 &\quad + D\delta(t-\tau)]u(\tau)d\tau
 \end{aligned} \tag{8}$$

The second expression involves the Dirac (or impulse or delta) function $\delta(t)$, and it is derived based on the basic property for $\delta(t)$, namely,

$$f(t) = \int_{-\infty}^{\infty} \delta(t-\tau)f(\tau)d\tau$$

It is clear that the matrix exponential e^{At} plays a central role in determining the response of a linear continuous-time, time-invariant system described by (1).

Given A , e^{At} may be determined using several methods including its defining series, diagonalization of A using a similarity transformation (PAP^{-1}), the Cayley-Hamilton theorem, using expressions involving the modes of the system ($e^{At} = \sum_{i=1}^n A_i e^{\lambda_i t}$ when A has n distinct eigenvalues λ_i ; $A_i = v_i \tilde{v}_i$ with $v_i, \tilde{v}_i$ the right and left eigenvectors of A that correspond to λ_i ($\tilde{v}_i v_j = 1, i = j$ and $\tilde{v}_i v_j = 0, i \neq j$)), or using Laplace transform ($e^{At} = \mathcal{L}^{-1}[(sI - A)^{-1}]$). See references below for detailed algorithms.

Equivalent State Variable Descriptions

Given

$$\dot{x} = Ax + Bu, \quad y = Cx + Du \tag{9}$$

consider the new state vector $\tilde{x}$ where

$$\tilde{x} = Px$$

with P a real nonsingular matrix. Substituting $x = P^{-1}\tilde{x}$ in (9), we obtain

$$\dot{\tilde{x}} = \tilde{A}\tilde{x} + \tilde{B}u, \quad y = \tilde{C}\tilde{x} + \tilde{D}u, \tag{10}$$

where

$$\tilde{A} = PAP^{-1}, \quad \tilde{B} = PB, \quad \tilde{C} = CP^{-1}, \quad \tilde{D} = D$$

The state variable descriptions (9) and (10) are called equivalent and P is the equivalence transformation. This transformation corresponds to a change in the basis of the state space, which is a vector space. Appropriately selecting P , one can simplify the structure of $\tilde{A}(= PAP^{-1})$; the matrices $\tilde{A}$ and A are called similar. When the eigenvectors of A are all linearly independent (this is the case, e.g., when all eigenvalues λ_i of A are distinct), then P may be found so that $\tilde{A}$ is diagonal. When e^{At} is to be determined, and $\tilde{A} = PAP^{-1} = \text{diag}[\lambda_i]$ ($\tilde{A}$ and A have the same eigenvalues), then

$$e^{At} = e^{P^{-1}\tilde{A}Pt} = P^{-1}e^{\tilde{A}t}P = P^{-1}\text{diag}[e^{\lambda_i t}]P.$$

Note that it can be easily shown that equivalent state space representations give rise to the same impulse response and transfer function (see [► Linear Systems: Continuous-Time Impulse Response Descriptions](#)).

Summary

State variable descriptions for continuous-time time-invariant systems are introduced and the state and output responses to inputs and initial conditions are derived. Equivalence of state variable representations is also discussed.

Recommended Reading

The state variable description of systems received wide acceptance in systems theory beginning in the late 1950s. This was primarily due to the work of R.E. Kalman and others in filtering theory and quadratic control theory and to the

work of applied mathematicians concerned with the stability theory of dynamical systems. For comments and extensive references on some of the early contributions in these areas, see Kailath (1980) and Sontag (1990). The use of state variable descriptions in systems and control opened the way for the systematic study of systems with multi-inputs and multi-outputs.

Linear Systems: Continuous-Time, Time-Varying State Variable Descriptions

Panos J. Antsaklis
Department of Electrical Engineering, University
of Notre Dame, Notre Dame, IN, USA

Abstract

Continuous-time processes that can be modeled by linear differential equations with time-varying coefficients can be written in terms of state variable descriptions of the form $\dot{x}(t) = A(t)x(t) + B(t)u(t)$, $y(t) = C(t)x(t) + D(t)u(t)$. The response of such systems due to

a given input and initial conditions is derived using the Peano-Baker series. Equivalence of state variable descriptions is also discussed.

Keywords

Continuous-time · Linear systems · State variable descriptions · Time-varying

Introduction

Dynamical processes that can be described or approximated by linear high-order ordinary differential equations with time-varying coefficients can also be described, via a change of variables, by state variable descriptions of the form

$$\begin{aligned}\dot{x}(t) &= A(t)x(t) + B(t)u(t); & x(t_0) &= x_0 \\ y(t) &= C(t)x(t) + D(t)u(t),\end{aligned}\quad (1)$$

where $x(t)$ ($t \in \mathbb{R}$, the set of reals) is a column vector of dimension n ($x(t) \in \mathbb{R}^n$) and $A(t)$, $B(t)$, $C(t)$, $D(t)$ are matrices with entries functions of time t . $A(t) = [a_{ij}(t)]$, $a_{ij}(t) : \mathbb{R} \rightarrow \mathbb{R}$. $A(t) \in \mathbb{R}^{n \times n}$, $B(t) \in \mathbb{R}^{n \times m}$, $C(t) \in \mathbb{R}^{p \times n}$, $D(t) \in \mathbb{R}^{p \times m}$. The input vector is $u(t) \in \mathbb{R}^m$ and the output vector is $y(t) \in \mathbb{R}^p$. The vector differential equation in (1) is the *state equation*, while the algebraic equation is the *output equation*.

The advantage of the state variable description (1) is that given an input $u(t)$, $t \geq 0$ and an initial condition $x(t_0) = x_0$, the state trajectory or motion for $t \geq t_0$ can be conveniently characterized. To derive the expressions, we first consider the homogenous state equation and the corresponding initial value problem.

Solving $\dot{x}(t) = A(t)x(t)$; $x(t_0) = x_0$

Consider the homogenous equation with the initial condition

$$x(t) = A(t)x(t); \quad x(t_0) = x_0 \quad (2)$$

where $x(t) = [x_1(t), \dots, x_n(t)]^T$ is the state (column) vector of dimension n and $A(t)$ is

an $n \times n$ matrix with entries functions of time that take on values from the field of reals ($A \in \mathbb{R}^{n \times n}$).

Under certain assumptions on the entries of $A(t)$, a solution of (2) exists and it is unique. These assumptions are satisfied, and a solution exists and is unique in the case, for example, when the entries of $A(t)$ are continuous functions of time. In the following we make this assumption.

To find the unique solution of (2), we use the *method of successive approximations* which when applied to

$$\dot{x}(t) = f(t, x(t)), \quad x(t_0) = x_0 \quad (3)$$

is described by

$$\begin{aligned} \phi_0(t) &= x_0 \\ \phi_m(t) &= x_0 + \int_{t_0}^t f(\tau, \phi_{m-1}(\tau)) d\tau, \quad m = 1, 2, \dots \end{aligned} \quad (4)$$

As $m \rightarrow \infty$, ϕ_m converges to the unique solution of (3), assuming the f satisfies certain conditions.

Applying the method of successive approximations to (2) yields

$$\begin{aligned} \phi_0(t) &= x_0 \\ \phi_1(t) &= x_0 + \int_{t_0}^t A(\tau)x_0 d\tau \\ \phi_2(t) &= x_0 + \int_{t_0}^t A(\tau)\phi_1(\tau)x_0 d\tau \\ &\vdots \\ \phi_m(t) &= x_0 + \int_{t_0}^t A(\tau)\phi_{m-1}(\tau)x_0 d\tau \end{aligned}$$

from which

$$\begin{aligned} \phi_m(t) &= \left[I + \int_{t_0}^t A(\tau_1) d\tau_1 \right. \\ &\quad \left. + \int_{t_0}^t A(\tau_1) \int_{t_0}^{\tau_1} A(\tau_2) d\tau_2 d\tau_1 + \dots \right] x_0 \end{aligned}$$

$$\begin{aligned} &+ \int_{t_0}^t A(\tau_1) \int_{t_0}^{\tau_1} A(\tau_2) \dots \int_{t_0}^{\tau_{m-1}} A(\tau_m) \\ &\quad d\tau_m \dots d\tau_1 \Big] x_0 \end{aligned}$$

When $m \rightarrow \infty$, and under the above continuity assumptions on $A(t)$, $\phi_m(t)$ converges to the unique solution of (2), i.e.,

$$\phi(t) = \Phi(t, t_0)x_0 \quad (5)$$

where

$$\begin{aligned} \Phi(t, t_0) &= I + \int_{t_0}^t A(\tau_1) d\tau_1 \\ &+ \int_{t_0}^t A(\tau_1) \left[\int_{t_0}^{\tau_1} A(\tau_2) d\tau_2 \right] d\tau_1 + \dots \end{aligned} \quad (6)$$

Note that $\Phi(t_0, t_0) = I$ and by differentiation it can be seen that

$$\dot{\phi}(t, t_0) = A(t)\phi(t, t_0), \quad (7)$$

as expected, since (5) is the solution of (2). The $n \times n$ matrix $\Phi(t, t_0)$ is called the *state transition matrix* of (2). The defining series (6) is called the Peano-Baker series.

Note that when $A(t) = A$, a constant matrix, then (6) becomes

$$\Phi(t, t_0) = I + \sum_{k=1}^{\infty} \frac{A^k(t-t_0)^k}{k!} \quad (8)$$

which is the defining series for the matrix exponential $e^{A(t-t_0)}$ (see ► [Linear Systems: Continuous-Time, Time-Invariant State Variable Descriptions](#)).

System Response

Based on the solution (5) of $\dot{x} = A(t)x(t)$, the solution of the non-homogenous equation

$$\dot{x}(t) = A(t)x(t) + B(t)u(t); \quad x(t_0) = x_0 \quad (9)$$

can be shown to be

$$\phi(t) = \Phi(t, t_0)x_0 + \int_{t_0}^t \Phi(t, \tau)B(\tau)u(\tau)d\tau. \quad (10)$$

Equation (10) is the *variation of constants formula*. This result can be shown via direct substitution of (10) into (9); note that $\phi(t) = \Phi(t_0, t_0)x_0 = x_0$. That (10) is a solution can also be shown using a change of variables in (9), namely,

$$z(t) = \Phi(t_0, t)x(t).$$

Equation (10) is the sum of two parts, the *state response* (when $u(t) = 0$ and the system is driven only by the initial state conditions) and the *input response* (when $x_0 = 0$ and the system is driven only by the input $u(t)$); this illustrates the linear system principle of superposition.

In view of (10), the output $y(t) (= C(t)x(t) + D(t)u(t))$ is

$$\begin{aligned} y(t) &= C(t)\Phi(t, t_0)x_0 \\ &\quad + \int_{t_0}^t C(t)\Phi(t, \tau)B(\tau)u(\tau)d\tau + D(t)u(t) \\ &= C(t)\Phi(t, t_0)x_0 + \int_{t_0}^t [C(t)\Phi(t, \tau)B(\tau) \\ &\quad + D(t)\delta(t - \tau)]u(\tau)d\tau \end{aligned}$$

The second expression involves the Dirac (or impulse or delta) function $\delta(t)$ and is derived based on the basic property for $\delta(t)$, namely,

$$f(t) = \int_{-\infty}^{+\infty} \delta(t - \tau)f(\tau)d\tau,$$

where $\delta(t - \tau)$ denotes an impulse applied at time $\tau = t$.

Properties of the State Transition Matrix $\Phi(t, t_0)$

In general it is difficult to determine $\Phi(t, t_0)$ explicitly; however, $\Phi(t, t_0)$ may be readily determined in a number of special cases including the cases in which $A(t) = A$, $A(t)$ is diagonal, $A(t)A(\tau) = A(\tau)A(t)$.

Consider $\dot{x} = A(t)x$. We can derive a number of important properties which are described below. It can be shown that given n linearly independent initial conditions x_{0i} , the corresponding n solutions $\phi_i(t)$ are also linearly independent. Let a *fundamental matrix* $\Psi(t)$ of $\dot{x} = A(t)x$ be an $n \times n$ matrix, the columns of which are a set of linearly independent solutions $\phi_1(t), \dots, \phi_n(t)$. The state transition matrix Φ is the fundamental matrix determined from solutions that correspond to the initial conditions $[1, 0, 0, \dots]^T, [0, 1, 0, \dots, 0]^T, \dots, [0, 0, \dots, 1]^T$ (recall that $\Phi(t_0, t_0) = I$). The following are properties of $\Phi(t, t_0)$:

- (i) $\Phi(t, t_0) = \Psi(t)\Psi^{-1}(t_0)$ with $\Psi(t)$ any fundamental matrix.
- (ii) $\Phi(t, t_0)$ is nonsingular for all t and t_0 .
- (iii) $\Phi(t, \tau) = \Phi(t, \sigma)\Phi(\sigma, \tau)$ (semigroup property).
- (iv) $[\Phi(t, t_0)]^{-1} = \Phi(t_0, t)$.

In the special case of time-invariant systems and $\dot{x} = Ax$, the above properties can be written in terms of the matrix exponential since

$$\Phi(t, t_0) = e^{A(t-t_0)}.$$

Equivalence of State Variable Descriptions

Given the system

$$\begin{aligned} \dot{x} &= A(t)x + B(t)u \\ y &= C(t)x + D(t)u \end{aligned} \quad (11)$$

consider the new state vector $\tilde{x}$

$$\tilde{x}(t) = P(t)x(t)$$

where $P^{-1}(t)$ exists and P and P^{-1} are continuous. Then the system

$$\begin{aligned}\dot{\tilde{x}} &= \tilde{A}(t)\tilde{x} + \tilde{B}(t)u \\ y &= \tilde{C}(t)\tilde{x} + \tilde{D}(t)u\end{aligned}$$

where

$$\begin{aligned}\tilde{A}(t) &= [P(t)A(t) + \dot{P}(t)]P^{-1}(t) \\ \tilde{B}(t) &= P(t)B(t) \\ \tilde{C}(t) &= C(t)P^{-1}(t) \\ \tilde{D}(t) &= D(t)\end{aligned}$$

is equivalent to (1). It can be easily shown that equivalent descriptions give rise to the same impulse responses.

Summary

State variable descriptions for continuous-time time-varying systems were introduced and the state and output responses to inputs and initial conditions were derived. The equivalence of state variable representations was also discussed.

Linear Systems: Discrete-Time Impulse Response Descriptions

Panos J. Antsaklis

Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

An important input-output description of a linear discrete-time system is its (discrete-time) impulse response (or pulse response), which is the response $h(k, k_0)$ to a discrete impulse applied at time k_0 . In time-invariant systems that are also causal and at rest at time zero, the impulse response is $h(k, 0)$, and its z -transform is the transfer function of the system. Expressions for $h(k, k_0)$ when the system is described by state variable equations are derived.

Keywords

At rest · Causal · Discrete-time · Discrete-time impulse response descriptions · Linear systems · Pulse response descriptions · Time-invariant · Time-varying · Transfer function descriptions

Introduction

Consider linear, discrete-time dynamical systems that can be described by

$$y(k) = \sum_{l=-\infty}^{+\infty} H(k, l)u(l) \quad (1)$$

where $k, l \in \mathbb{Z}$ is the set of integers, the output is $y(k) \in \mathbb{R}^p$, the input is $u(k) \in \mathbb{R}^m$, and $H(k, l) : \mathbb{Z} \times \mathbb{Z} \rightarrow \mathbb{R}^{p \times m}$. For instance, any system that can be written in state variable form

$$\begin{aligned} x(k+1) &= A(k)x(k) + B(k)u(k) \\ y(k) &= C(k)x(k) + D(k)u(k) \end{aligned} \quad (2)$$

or

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k) \\ y(k) &= Cx(k) + Du(k) \end{aligned} \quad (3)$$

can be represented by (1). Note that it is assumed that at $l = -\infty$, the system is at rest, i.e., no energy is stored in the system at time $-\infty$.

Define the discrete-time impulse (or unit pulse) as

$$\delta(k) = \begin{cases} 1 & k = 0 \\ 0 & k \neq 0 \end{cases}, k \in \mathbb{Z}$$

and consider a single-input, single-output system:

$$y(k) = \sum_{l=-\infty}^{+\infty} h(k, l)u(l) \quad (4)$$

If $u(l) = \delta(\hat{l} - l)$, that is, the input is a unit pulse applied at $l = \hat{l}$, then the output is

$$y_I(k) = h(k, \hat{l}),$$

i.e., $h(k, \hat{l})$ is the output at time k when a unit pulse is applied at time $\hat{l}$.

So in (4) $h(k, l)$ is the response at time k to a discrete-time impulse (unit pulse) applied at time l . $h(k, l)$ is the *discrete-time impulse response* of the system. Clearly if $h(k, l)$ is known, the response of the system to any input can be

determined via (4). So $h(k, l)$ is an input/output description of the system.

Equation (1) is a generalization of (4) for the multi-input, multi-output case. If we let all the components of $u(l)$ in (1) be zero except for the j th component, then

$$y_i(k) = \sum_{l=-\infty}^{+\infty} h_{ij}(k, l)u_j(l) \quad (5)$$

$h_{ij}(k, l)$ denotes the response of the i th component of the output of system (1) at time k due to a discrete impulse applied to the j th component of the input at time l with all remaining components of the input being zero. $H(k, l) = [h_{ij}(k, l)]$ is called the *impulse response matrix* of the system.

If it is known that system (1) is *causal*, then the output will be zero before an input is applied. Therefore,

$$H(k, l) = 0, \quad \text{for } k < l, \quad (6)$$

and so when causality is present, (1) becomes

$$y(k) = \sum_{l=-\infty}^k H(k, l)u(l). \quad (7)$$

A system described by (1) is at rest at $k = k_0$ if $u(k) = 0$ for $k \geq k_0$ implies $y(k) = 0$ for $k \geq k_0$. For a system at rest at $k = k_0$, (7) becomes

$$y(k) = \sum_{l=k_0}^k H(k, l)u(l). \quad (8)$$

If system (1) is time-invariant, then $H(k, l) = H(k - l, 0)$ (also written as $H(k - l)$) since only the time elapsed $(k - l)$ from the application of the discrete-time impulse is important. Then (8) becomes

$$y(k) = \sum_{l=0}^k H(k - l)u(l), \quad k \geq 0, \quad (9)$$

where we chose $k_0 = 0$ without loss of generality. Equation (9) is the description for casual, time-invariant systems, at rest at $k = 0$.

Equation (9) is a convolution sum and if we take the (one-sided or unilateral) z -transform of both sides,

$$\hat{y}(z) = \hat{H}(z)\hat{u}(z), \quad (10)$$

where $\hat{y}(z)$, $\hat{u}(z)$ are the z -transforms of $y(k)$, $u(k)$ and $\hat{H}(z)$ is the z -transform of the discrete-time impulse response $H(k)$. $\hat{H}(z)$ is the *transfer function matrix* of the system. Note that the transfer function of a linear, time-invariant system is defined as the rational matrix $\hat{H}(z)$ that satisfies (10) for any input and its corresponding output assuming zero initial conditions.

Connections to State Variable Descriptions

When a system is described by (2), then

$$y(k) = \sum_{l=k_0}^{k-1} C(k)\Phi(k, l+1)B(l)u(l) + D(k)u(k), \quad k > k_0 \quad (11)$$

where it was assumed that $x(k_0) = 0$, i.e., the system is at rest at k_0 . Here $\Phi(k, l) (= A(k-1) \cdots A(l))$ is the state transition matrix of the system.

Comparing (11) with (8), the discrete-time impulse response of the system is

$$H(k, l) = \begin{cases} C(k)\Phi(k, l+1)B(l) & k > l \\ D(k) & k = l \\ 0 & k < l \end{cases} \quad (12)$$

Similarly, when the system is time-invariant and is described by (3),

$$y(k) = \sum_{l=k_0}^{k-1} CA^{k-(l+1)}Bu(l) + Du(k), \quad k > k_0 \quad (13)$$

where $x(k_0) = 0$ and

$$H(k, l) = H(k-l) = \begin{cases} CA^{k-(l+1)}B & k > l \\ D & k = l \\ 0 & k < l \end{cases} \quad (14)$$

When $l = 0$ (taking the time when the discrete impulse is applied to be zero, $l = 0$), the discrete-time impulse response is

$$H(k) = \begin{cases} CA^{k-1}B & k > 0 \\ D & k = 0 \\ 0 & k < 0 \end{cases} \quad (15)$$

Taking (one-sided or unilateral) z -transforms of both sides in (15),

$$\hat{H}(z) = C(zI - A)^{-1}B + D \quad (16)$$

which is the transfer function matrix in terms of the coefficient matrices in the state variable description (3). Note that (16) can also be derived directly from (3) by assuming zero initial conditions ($x(0) = 0$) and taking z -transforms of both sides.

Finally, it is easy to show that equivalent state variable descriptions give rise to the same discrete-impulse response.

Summary

The discrete-time impulse response is an external, input-output description of linear, discrete-time systems. When the system is time-invariant, the z -transform of the impulse response $h(k, 0)$ (which is the output response at time k due to a discrete impulse applied at time zero with initial conditions taken to be zero) is the transfer function – another very common input-output description. The relationships to the state variable descriptions were shown.

Linear Systems: Discrete-Time, Time-Invariant State Variable Descriptions

Panos J. Antsaklis
 Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Discrete-time processes that can be modeled by linear difference equations with constant coefficients can also be described in a systematic way in terms of state variable descriptions of the form $x(k+1) = Ax(k) + Bu(k)$, $y(k) = Cx(k) + Du(k)$. The response of such systems due to a given input and subject to initial conditions is derived. Equivalence of state variable descriptions is also discussed.

Keywords

Discrete-time · Linear systems · State variable descriptions · Time-invariant

Introduction

Discrete-time systems arise in a variety of ways in the modeling process. There are systems that

are inherently defined only at discrete points in time; examples include digital devices, inventory systems, economic systems such as banking where interest is calculated and added to savings accounts at discrete time interval, etc. There are also systems that describe continuous-time systems at discrete points in time; examples include simulations of continuous processes using digital computers and feedback control systems that employ digital controllers and give rise to sampled-data systems.

Linear, discrete-time, time-invariant systems can be modeled via state variable equations, namely,

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k); \quad x(0) = x_0 \\ y(k) &= Cx(k) + Du(k) \end{aligned} \quad (1)$$

where $k \in \mathbb{Z}$, the set of integers, the state vector $x \in \mathbb{R}^n$, i.e., an n dimensional column vector; $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, $D \in \mathbb{R}^{p \times m}$ are matrices with entries of real numbers; and $y(k) \in \mathbb{R}^p$, $u(k) \in \mathbb{R}^m$ the output and the input, respectively. The vector difference equation in (1) is the *state equation* and the algebraic equation is the *output equation*.

Note that (1) could have been equivalently written as $x(l) = Ax(l-1) + Bu(l-1)$ where $l = k+1$ and $x(l-1)$ is an easily visualized delayed version of $x(l)$; this is a form more common in signal processing (where a two-sided or bilateral z -transform is used). In control where we assume a known initial condition at time equal to zero (and one-sided or unilateral z -transform is taken), the form in (1) is common.

Similar to the continuous-time case, (1) can be derived from a set of high-order difference equations by introducing the state variables $x(k) = [x_1(k), \dots, x_n(k)]^T$. Description (1) can also be derived from continuous-time system descriptions by sampling (see ► [Sampled-Data Systems](#)).

The advantage of the above state variable description is that given any input $u(k)$ and initial conditions $x(0)$, its solution (state trajectory or motion) can be conveniently and systematically characterized. This is done below. We first

consider the solutions of the homogenous equation $x(k+1) = Ax(k)$.

Solving $x(k+1) = Ax(k)$; $x(0) = x_0$

Consider the homogenous equation

$$x(k+1) = Ax(k); \quad x(0) = x_0 \quad (2)$$

where $k \in \mathbb{Z}^+$ is a nonnegative integer, $x(k) = [x_1(k), \dots, x_n(k)]^T$ is the state column vectors of dimension n , and A is an $n \times n$ matrix with entries real numbers (i.e., $A \in \mathbb{R}^{n \times n}$).

Write (2) for $k = 0, 1, 2, \dots$, namely, $x(1) = Ax(0)$, $x(2) = Ax(1) = A^2x(0)$, $\dots$ to derive the solution

$$x(k) = A^k x(0), \quad k \geq 0 \quad (3)$$

This result can be shown formally by induction. Note that $A^0 = I$ by convention and so (3) also satisfies the initial condition.

If the initial time were some (integer) k_0 instead of zero, then the solution would be

$$x(k) = A^{k-k_0} x(k_0), \quad k \geq k_0 \quad (4)$$

The solution can be written as

$$\begin{aligned} x(k) &= \Phi(k, k_0)x(k_0) \\ &= \Phi(k - k_0, 0)x(k_0), \quad k \geq k_0 \end{aligned} \quad (5)$$

where $\Phi(k, k_0)$ is the state transition matrix and it equals $\Phi(k, k_0) = A^{k-k_0}$. Note that for time-invariant systems, the initial time k_0 can always be taken to be zero without loss of generality; this is because the behavior depends only on the time elapsed ($k - k_0$) and not on the actual initial time k_0 .

In view of (3), it is clear that A^k plays an important role in the solutions of the difference state equations that describe linear, discrete-time, time-invariant systems; it is actually analogous to the role e^{At} plays in the solutions of the linear differential state equations that describe linear, continuous-time, time-invariant systems.

Notice that in (3), $k \geq 0$. This is so because A^k for $k < 0$ may not exist; this is the case, for example, when A is a singular matrix – it has at least one eigenvalue at the origin. In contrast, e^{At} exists for any t positive or negative. The implication is that in discrete-time systems we may not be able to determine uniquely the initial past state $x(0)$ from a current state value $x(k)$; in contrast, in continuous-time systems, it is always possible to go backwards in time.

There are several methods to calculate A^k that mirror the methods to calculate e^{At} . One could, for example, use similarity transformations, or the z -transform. When all eigenvectors of A are linearly independent (this is the case, e.g., when all eigenvalues λ_i of A are distinct), then a similarity transformation exists so that

$$PAP^{-1} = \tilde{A} = \text{diag}[\lambda_i].$$

Then

$$A^k = P^{-1} \tilde{A}^k P = P^{-1} \begin{bmatrix} \lambda_1^k & & \\ & \ddots & \\ & & \lambda_n^k \end{bmatrix} P.$$

Alternatively, using the z -transforms, $A^k = z^{-1}\{z(zI - A)^{-1}\}$. Also when the eigenvalues λ_i of A are distinct, then

$$A^k = \sum_{i=1}^n A_i \lambda_i^k,$$

where $A_i = v_i \tilde{v}_i$ with $v_i, \tilde{v}_i$ the right and left eigenvectors of A that correspond to λ_i . Note that

$$\begin{bmatrix} \tilde{v}_1 \\ \vdots \\ \tilde{v}_n \end{bmatrix} = [v_1 \cdots v_n]^{-1},$$

$A_i \lambda_i^k$ are the modes of the system. One could also use the Cayley-Hamilton theorem to determine A^k .

System Response

Consider the description (1). The response can be easily derived by writing the equation for $k = 0, 1, 2, \dots$ and substituting or formally by induction. It is

$$x(k) = A^k x(0) + \sum_{j=0}^{k-1} A^{k-(j+1)} B u(j), \quad k > 0 \quad (6)$$

and

$$\begin{aligned} y(k) &= C A^k x(0) + \sum_{j=0}^{k-1} C A^{k-(j+1)} B u(j) \\ &\quad + D u(k), \quad k > 0 \\ y(0) &= C x(0) + D u(0). \end{aligned} \quad (7)$$

Note that (6) can also be written as

$$x(k) = A^k x(0) + [B, AB, \dots, A^{k-1}B] \begin{bmatrix} u(k-1) \\ \vdots \\ u(0) \end{bmatrix}. \quad (8)$$

Clearly the response is the sum of two components, one due to the initial condition (state response) and one due to the input (input response). This illustrates the linear system principle of superposition.

If the initial time is k_0 and (4) is used, then

$$\begin{aligned} y(k) &= C A^{k-k_0} x(k_0) + \sum_{j=k_0}^{k-1} C A^{k-(j+1)} B u(j) \\ &\quad + D u(k), \quad k > k_0 \\ y(k_0) &= C x(k_0) + D u(k_0). \end{aligned} \quad (9)$$

Equivalence of State Variable Descriptions

Given description (1), consider the new state vector $\tilde{x}$ where

$$\tilde{x}(k) = P x(k)$$

with $P \in \mathbb{R}^{n \times n}$ a real nonsingular matrix.

Substituting $x = P^{-1} \tilde{x}$ in (1), we obtain

$$\begin{aligned} \tilde{x}(k+1) &= \tilde{A} \tilde{x}(k) + \tilde{B} u(k) \\ y(k) &= \tilde{C} \tilde{x}(k) + \tilde{D} u(k) \end{aligned} \quad (10)$$

where

$$\tilde{A} = P A P^{-1}, \quad \tilde{B} = P B, \quad \tilde{C} = C P^{-1}, \quad \tilde{D} = D$$

The state variable descriptions (1) and (9) are called equivalent and P is the equivalence transformation matrix. This transformation corresponds to a change in the basis of the state space, which is a vector space. Appropriately selecting P one can simplify the structure of $\tilde{A}$ ($= P A P^{-1}$). It can be easily shown that equivalent description gives rise to the same discrete impulse response and transfer function.

Summary

State variable descriptions for discrete-time, time-invariant systems were introduced and the state and output responses to inputs and initial conditions were derived. The equivalence of state variable representations was also discussed.

Abstract

Discrete-time processes that can be modeled by linear difference equations with time-varying coefficients can be written in terms of state variable descriptions of the form $x(k+1) = A(k)x(k) + B(k)u(k)$, $y(k) = C(k)x(k) + D(k)u(k)$. The response of such systems due to a given input and initial conditions is derived. Equivalence of state variable descriptions is also discussed.

Keywords

Discrete-time · Linear systems · State variable descriptions · Time-varying

Introduction

Discrete-time systems arise in a variety of ways in the modeling process. There are systems that are inherently defined only at discrete points in

time; examples include digital devices, inventory systems, and economic systems such as banking where interest is calculated and added to savings accounts at discrete time interval. There are also systems that describe continuous-time systems at discrete points in time; examples include simulations of continuous processes using digital computers and feedback control systems that employ digital controllers and give rise to sampled-data systems.

Dynamical processes that can be described or approximated by linear difference equations with time-varying coefficients can also be described, via a change of variables, by state variable descriptions of the form

$$\begin{aligned} x(k+1) &= A(k)x(k) + B(k)u(k); \quad x(k_0) = x_0 \\ y(k) &= C(k)x(k) + D(k)u(k). \end{aligned} \quad (1)$$

Above, the state vector $x(k)$ ($k \in \mathbb{Z}$, the set of integers) is a column vector of dimension n ($x(k) \in \mathbb{R}^n$); the output is $y(k) \in \mathbb{R}^m$ and the input is $u(k) \in \mathbb{R}^m$. $A(k)$, $B(k)$, $C(k)$, and $D(k)$ are matrices with entries functions of time k , $A(k) = [a_{ij}(k)]$, $a_{ij}(k) : \mathbb{Z} \rightarrow \mathbb{R}$ ($A(k) \in \mathbb{R}^{n \times n}$, $B(k) \in \mathbb{R}^{n \times m}$, $C(k) \in \mathbb{R}^{p \times n}$, $D(k) \in \mathbb{R}^{p \times m}$). The vector difference equation in (1) is the state equation, while the algebraic equation is the output equation. Note that in the time-invariant case, $A(k) = A$, $B(k) = B$, $C(k) = C$, and $D(k) = D$.

The advantage of the state variable description (1) is that given an input $u(k)$, $k \geq k_0$ and an initial condition $x(k_0) = x_0$, the state trajectories or motions for $k \geq k_0$ can be conveniently characterized. To determine the expressions, we first consider the homogeneous state equation and the corresponding initial value problem.

Solving $x(k+1) = A(k)x(k)$; $x(k_0) = x_0$

Consider the homogenous equation

$$x(k+1) = A(k)x(k); \quad x(k_0) = x_0 \quad (2)$$

Note that

$$\begin{aligned}
 x(k_0 + 1) &= A(k_0)x(k_0) \\
 x(k_0 + 2) &= A(k_0 + 1)A(k_0)x(k_0) \\
 &\vdots \\
 x(k) &= A(k-1)A(k-2) \cdots A(k_0)x(k_0) \\
 &= \prod_{j=k_0}^{k-1} A(j)x(k_0), \quad k > k_0
 \end{aligned}$$

This result can be shown formally by induction. The solution of (2) is then

$$x(k) = \Phi(k, k_0)x(k_0), \quad (3)$$

where $\Phi(k, k_0)$ is the *state transition matrix* of (2) given by

$$\Phi(k, k_0) = \prod_{j=k_0}^{k-1} A(j), \quad k > k_0; \quad \Phi(k_0, k_0) = I. \quad (4)$$

Note that in the time-invariant case, $\Phi(k, k_0) = A^{k-k_0}$.

System Response

Consider now the state equation in (1). It can be easily shown that the solution is

$$\begin{aligned}
 x(k) &= \Phi(k, k_0)x(k_0) \\
 &+ \sum_{j=k_0}^{k-1} \Phi(k, j+1)B(j)u(j), \quad k > k_0,
 \end{aligned} \quad (5)$$

and the response $y(k)$ of (1) is

$$\begin{aligned}
 y(k) &= C(k)\Phi(k, k_0)x(k_0) \\
 &+ C(k) \sum_{j=k_0}^{k-1} \Phi(k, j+1)B(j)u(j) \\
 &+ D(k)u(k), \quad k > k_0,
 \end{aligned} \quad (6)$$

and

$$y(k_0) = C(k_0)x(k_0) + D(k_0)u(k_0).$$

Equation (5) is the sum of two parts, the *state response* (when $u(k) = 0$ and the system is driven only by the initial state conditions) and the *input response* (when $x(k_0) = 0$ and the system is driven only by the input $u(k)$); this illustrates the linear systems principle of superposition.

Equivalence of State Variable Descriptions

Given (1), consider the new state vector $\tilde{x}$ where

$$\tilde{x}(k) = P(k)x(k)$$

where $P^{-1}(k)$ exists. Then

$$\begin{aligned}
 \tilde{x}(k+1) &= \tilde{A}(k)\tilde{x}(k) + \tilde{B}(k)u(k) \\
 y(k) &= \tilde{C}(k)\tilde{x}(k) + \tilde{D}(k)u(k)
 \end{aligned} \quad (7)$$

where

$$\begin{aligned}
 \tilde{A}(k) &= P(k+1)A(k)P^{-1}(k), \\
 \tilde{B}(k) &= P(k+1)B(k), \\
 \tilde{C}(k) &= C(k)P^{-1}(k), \\
 \tilde{D}(k) &= D(k)
 \end{aligned}$$

is equivalent to (1). It can be easily shown that equivalent descriptions give rise to the same discrete impulse responses.

Summary

State variable descriptions for linear discrete-time time-varying systems were introduced and the state and output responses to inputs and initial conditions were derived. The equivalence of state variable representations was also discussed.

Recommended Reading

The state variable descriptions received wide acceptance in systems theory beginning in the late 1950s. This was primarily due to the work of R.E. Kalman. For historical comments and extensive references, see Kailath (1980). The use of state variable descriptions in systems and control opened the way for the systematic study of systems with multi-inputs and multi-outputs.

LMI Approach to Robust Control

Kang-Zhi Liu

Department of Electrical and Electronic Engineering, Chiba University, Chiba, Japan

Abstract

In the analysis and design of robust control systems, LMI method plays a fundamental role. This article gives a brief introduction to

this topic. After the introduction of LMI, it is illustrated how a control design problem is related with matrix inequality. Then, two methods are explained on how to transform a control problem characterized by matrix inequalities to LMIs, which is the core of the LMI approach. Based on this knowledge, the LMI solutions to various kinds of robust control problems are illustrated. Included are $\mathcal{H}_\infty$ and $\mathcal{H}_2$ control, regional pole placement, and gain-scheduled control.

Keywords

Gain-scheduled control · $\mathcal{H}_\infty$ and $\mathcal{H}_2$ control · LMI · Multi-objective control · Regional pole placement · Robust control

Introduction of LMI

A matrix inequality in a form of

$$F(x) = F_0 + \sum_{i=1}^m x_i F_i > 0 \quad (1)$$

is called an LMI (linear matrix inequality). Here, $x = [x_1 \cdots x_m]$ is the unknown vector and $F_i (i = 1, \dots, m)$ is a symmetric matrix. $F(x)$ is an affine function of x . The inequality means that $F(x)$ is positive definite.

LMI can be solved effectively by numerical algorithms such as the famous interior point method (Nesterov and Nemirovskii 1994). MATLAB has an LMI toolbox (Gahinet et al. 1995) tailored for solving the related control problems. Boyd et al. (1994) provide detailed theoretic fundamentals of LMI. A comprehensive and up-to-date treatment on the applications of LMI in robust control is covered in Liu and Yao (2014).

The notation $\text{He}(A) = A + A^T$ is used to simplify the presentation of large matrices; $A_\perp$ is a matrix whose columns form the basis of the kernel space of A , i.e., $AA_\perp = 0$. Further, $A \otimes B$ denotes the Kronecker product of matrices (A, B) .

Control Problems and LMI

In control problems, it is often the case that the variables are matrices. For example, the necessary and sufficient condition for the stability of a linear system $\dot{x}(t) = Ax(t)$ is that there exists a positive-definite matrix P satisfying the inequality $AP + PA^T < 0$. Although this is different from the LMI of Eq. (1) in form, it can be converted to Eq. (1) equivalently by using a basis of symmetric matrices.

Next, consider the stabilization of system $\dot{x} = Ax + Bu$ by a state feedback $u = Fx$. The closed-loop system is $\dot{x} = (A + BF)x$. Therefore, the stability condition is that there exist a positive-definite matrix P and a feedback gain matrix F satisfying the inequality

$$(A + BF)P + P(A + BF)^T < 0. \quad (2)$$

In this inequality, FP , the product of unknown variables F and P , appears. Such matrix inequality is called a *bilinear matrix inequality*, or *BMI* for short. BMI problem is non-convex and difficult to solve. There are mainly two methods for transforming a BMI into an LMI: variable elimination and variable change.

From BMI to LMI: Variable Elimination

The method of variable elimination is good at optimizing single-objective problems. This method is based on the theorem below (Gahinet and Apkarian 1994).

Lemma 1 *Given real matrices E, F, G with G being symmetric, the inequality*

$$E^T XF + F^T X^T E + G < 0 \quad (3)$$

has a solution X if and only if the following two inequalities hold simultaneously

$$E_{\perp}^T G E_{\perp} < 0, \quad F_{\perp}^T G F_{\perp} < 0. \quad (4)$$

Application of this theorem to the previous stabilization problem (2) yields $(B^T)_{\perp}^T (AP + PA^T)(B^T)_{\perp} < 0$, which is an LMI about P . Once P is obtained, it may be substituted back into the inequality (2) and solve for F .

For output feedback problems, it is often needed to construct a new matrix from two given matrices in solving a control problem with LMI approach. The method is given by the following lemma.

Lemma 2 *Given two n -dimensional positive-definite matrices X and Y , a $2n$ -dimensional positive-definite matrix $\mathbb{P}$ satisfying the conditions*

$$\mathbb{P} = \begin{bmatrix} Y & * \\ * & * \end{bmatrix}, \quad \mathbb{P}^{-1} = \begin{bmatrix} X & * \\ * & * \end{bmatrix}$$

can be constructed if and only if

$$\begin{bmatrix} X & I \\ I & Y \end{bmatrix} > 0. \quad (5)$$

Factorizing $Y - X^{-1}$ as FF^T , a solution is given by

$$\mathbb{P} = \begin{bmatrix} Y & F \\ F^T & I \end{bmatrix}.$$

As an example of output feedback control design, let us consider the stabilization of the plant

$$\dot{x}_p = Ax_p + Bu, \quad y = Cx_p \quad (6)$$

with a full-order dynamic controller

$$\dot{x}_K = A_K x_K + B_K y, \quad u = C_K x_K + D_K y. \quad (7)$$

The closed-loop system is

$$\begin{bmatrix} \dot{x}_p \\ \dot{x}_K \end{bmatrix} = A_c \begin{bmatrix} x_p \\ x_K \end{bmatrix}, \quad A_c = \begin{bmatrix} A + BD_K C & BC_K \\ B_K C & A_K \end{bmatrix}. \quad (8)$$

The stability condition is that the matrix inequality

$$A_c^T \mathbb{P} + \mathbb{P} A_c < 0 \quad (9)$$

has a solution $\mathbb{P} > 0$. To apply the variable elimination method, we need to put all coefficient matrices of the controller into a single matrix.

This is done as follows:

$$A_c = \bar{A} + \bar{B}\mathcal{K}\bar{C}, \quad \mathcal{K} = \begin{bmatrix} D_K & C_K \\ B_K & A_K \end{bmatrix} \quad (10)$$

in which $\bar{A} = \text{diag}(A, 0)$, $\bar{B} = \text{diag}(B, I)$, and $\bar{C} = \text{diag}(C, I)$, all being block diagonal. Then, based on Lemma 1, the stability condition reduces to the existence of symmetric matrices X , Y satisfying LMIs

$$(B^T)_{\perp}^T (AX + XA^T) (B^T)_{\perp} < 0 \quad (11)$$

$$(C_{\perp})^T (YA + A^T Y) C_{\perp} < 0. \quad (12)$$

Meanwhile, the positive definiteness of matrix $\mathbb{P}$ is guaranteed by Eq. (5) in Lemma 2.

From BMI to LMI: Variable Change

We may also use the method of variable change to transform a BMI into an LMI. This method is good at multi-objective optimization.

The detail is as follows (Gahinet 1996). A positive-definite matrix can always be factorized as the quotient of two triangular matrices, i.e.,

$$\mathbb{P}\Pi_1 = \Pi_2, \quad \Pi_1 = \begin{bmatrix} X & I \\ M^T & 0 \end{bmatrix}, \quad \Pi_2 = \begin{bmatrix} I & Y \\ 0 & N^T \end{bmatrix}. \quad (13)$$

$\mathbb{P} > 0$ is guaranteed by Eq. (5) for a full-order controller. Further, the matrices M , N are computed from $MN^T = I - XY$. Consequently, they are nonsingular.

An equivalent inequality $\Pi_1^T A_c^T \Pi_2 + \Pi_2^T A_c \Pi_1 < 0$ is obtained by multiplying Eq. (9) with Π_1^T and Π_1 . After a change of variables, this inequality reduces to an LMI

$$\text{He} \begin{bmatrix} AX + BC & A + B\mathbb{D}C + \mathbb{A}^T \\ 0 & YA + \mathbb{B}C \end{bmatrix} < 0. \quad (14)$$

LMI Approach to Robust Control, Fig. 1
Generalized feedback system

The new variables $\mathbb{A}$, $\mathbb{B}$, $\mathbb{C}$, $\mathbb{D}$ are set as

$$\begin{aligned} \mathbb{A} &= NA_K M^T + NB_K CX + YBC_K M^T \\ &\quad + Y(A + BD_K C)X \\ \mathbb{B} &= NB_K + YBD_K, \quad \mathbb{C} = C_K M^T \\ &\quad + D_K CX, \quad \mathbb{D} = D_K. \end{aligned} \quad (15)$$

The coefficient matrices of the controller become

$$\begin{aligned} D_K &= \mathbb{D}, \quad C_K = (\mathbb{C} - D_K CX)M^{-T}, \\ B_K &= N^{-1}(\mathbb{B} - YBD_K) \\ A_K &= N^{-1}(\mathbb{A} - NB_K CX - YBC_K M^T \\ &\quad - Y(A + BD_K C)X)M^{-T}. \end{aligned} \quad (16)$$

$\mathcal{H}_2$ and $\mathcal{H}_\infty$ Control

In system optimization, $\mathcal{H}_2$ and $\mathcal{H}_\infty$ norms are the most popular and effective performance indices. $\mathcal{H}_2$ norm of a transfer function is closely related with the squared area of its impulse response. So, a smaller $\mathcal{H}_2$ norm implies a faster response. Meanwhile, $\mathcal{H}_\infty$ norm of a transfer function is the largest magnitude of its frequency response. Hence, for a transfer function from the disturbance to the controlled output, a smaller $\mathcal{H}_\infty$ norm guarantees a better disturbance attenuation.

Usually $\mathcal{H}_2$ and $\mathcal{H}_\infty$ optimization problems are treated in the generalized feedback system of Fig. 1. Here, the generalized plant $G(s)$ includes the nominal plant, the performance index, and the weighting functions.

Let the generalized plant $G(s)$ be

$$G(s) = \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} (sI - A)^{-1} \begin{bmatrix} B_1 & B_2 \end{bmatrix} + \begin{bmatrix} D_{11} & D_{12} \\ D_{21} & 0 \end{bmatrix}. \quad (17)$$

Further, the stabilizability of (A, B_2) and the detectability of (C_2, A) are assumed. The closed-loop transfer matrix from the disturbance

w to the performance output z is denoted by

$$H_{zw}(s) = C_c(sI - A_c)^{-1}B_c + D_c. \quad (18)$$

The condition for $H_{zw}(s)$ to have an $\mathcal{H}_2$ norm less than γ , i.e., $\|H_{zw}\|_2 < \gamma$, is that there are symmetric matrices $\mathbb{P}$ and W satisfying

$$\begin{bmatrix} \mathbb{P}A_c + A_c^T\mathbb{P} & C_c^T \\ C_c & -I \end{bmatrix} < 0, \quad \begin{bmatrix} W & B_c^T\mathbb{P} \\ \mathbb{P}B_c & \mathbb{P} \end{bmatrix} > 0 \quad (19)$$

as well as $\text{Tr}(W) < \gamma^2$. Here, $\text{Tr}(W)$ denotes the trace of matrix W , i.e., the sum of its diagonal entries.

The LMI solution is derived via the application of the variable change method, as given below.

Theorem 1 Suppose that $D_{11} = 0$. The $\mathcal{H}_2$ control problem is solvable if and only if there exist symmetric matrices X, Y, W and matrices $\mathbb{A}, \mathbb{B}, \mathbb{C}$ satisfying the following LMIs:

$$\text{He} \begin{bmatrix} AX + B_2\mathbb{C} & 0 & 0 \\ A^T + \mathbb{A} & YA + \mathbb{B}C_2 & 0 \\ C_1X + D_{12}\mathbb{C} & C_1 & -\frac{1}{2}I \end{bmatrix} < 0 \quad (20)$$

$$\begin{bmatrix} W & B_1^T & B_1^TY \\ B_1 & X & I \\ YB_1 & I & Y \end{bmatrix} > 0, \quad \text{Tr}(W) < \gamma^2. \quad (21)$$

When the LMI Eqs. (20) and (21) have solutions, an $\mathcal{H}_2$ controller is given by Eq. (16) by setting $\mathbb{D} = 0$.

The $\mathcal{H}_\infty$ control problem is to design a controller so that $\|H_{zw}\|_\infty < \gamma$. The starting point of $\mathcal{H}_\infty$ control is the famous bounded real lemma, which states that $H_{zw}(s)$ has an $\mathcal{H}_\infty$ normless

than γ if and only if there is a positive-definite matrix $\mathbb{P}$ satisfying

$$\begin{bmatrix} A_c^T\mathbb{P} + \mathbb{P}A_c & \mathbb{P}B_c & C_c^T \\ B_c^T\mathbb{P} & -\gamma I & D_c^T \\ C_c & D_c & -\gamma I \end{bmatrix} < 0. \quad (22)$$

There are two kinds of LMI solutions to this control problem: one based on variable elimination and one based on variable change.

To state the first solution, define the following matrices first:

$$N_Y = [C_2 \ D_{21}]_\perp, \quad N_X = [B_2^T \ D_{12}^T]_\perp. \quad (23)$$

Theorem 2 The $\mathcal{H}_\infty$ control problem has a solution if and only if Eq. (5) and the following LMIs have positive-definite solutions X, Y :

$$\begin{bmatrix} N_X^T & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} AX + XA^T & XC_1^T & B_1 \\ C_1X & -\gamma I & D_{11} \\ B_1^T & D_{11}^T & -\gamma I \end{bmatrix} \times \begin{bmatrix} N_X & 0 \\ 0 & I \end{bmatrix} < 0 \quad (24)$$

$$\begin{bmatrix} N_Y^T & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} YA + A^TY & YB_1 & C_1^T \\ B_1^TY & -\gamma I & D_{11}^T \\ C_1 & D_{11} & -\gamma I \end{bmatrix} \times \begin{bmatrix} N_Y & 0 \\ 0 & I \end{bmatrix} < 0. \quad (25)$$

Once a matrix $\mathbb{P}$ is computed according to Lemma 2, Eq. (22) becomes an LMI and its solution yields the controller.

The second solution is given below.

Theorem 3 The $\mathcal{H}_\infty$ control problem has a solution if and only if Eq. (5) and the following LMI have solutions X, Y and $\mathbb{A}, \mathbb{B}, \mathbb{C}, \mathbb{D}$:

$$\text{He} \begin{bmatrix} AX + B_2\mathbb{C} & A + B_2\mathbb{D}C_2 & B_1 + B_2\mathbb{D}D_{21} & 0 \\ \mathbb{A} & YA + \mathbb{B}C_2 & YB_1 + \mathbb{B}D_{21} & 0 \\ 0 & 0 & -\frac{\gamma}{2}I & 0 \\ C_1X + D_{12}\mathbb{C} & C_1 + D_{12}\mathbb{D}C_2 & D_{11} + D_{12}\mathbb{D}D_{21} & -\frac{\gamma}{2}I \end{bmatrix} < 0. \quad (26)$$

The controller is given by Eq. (16).

Regional Pole Placement

The location of system poles determines the response quality. However, for uncertain systems it is impossible to place the closed-loop poles at fixed points because they move with the variation of the plant. Nevertheless, it is still possible to place the closed-loop poles inside a region. For convex regions characterized by LMI, the design method is mature and proven effective in practice.

Let us see how to characterize a convex region. It is easy to know that a complex number z is inside the disk of Fig. 2a if and only if it satisfies

$$\begin{bmatrix} -r & z + c \\ \bar{z} + c & -r \end{bmatrix} < 0.$$

Similarly, z is inside the sector of Fig. 2b if and only if

$$\begin{bmatrix} (z + \bar{z}) \sin \theta & (z - \bar{z}) \cos \theta \\ -(z - \bar{z}) \cos \theta & (z + \bar{z}) \sin \theta \end{bmatrix} < 0.$$

Generally, the set of complex number z characterized by

$$D = \{z \in \mathbb{C} | L + zM + \bar{z}M^T < 0\} \quad (27)$$

is called an LMI region, in which L is a symmetric matrix. For the dynamic system

$$\dot{x} = Ax, \quad (28)$$

LMI Approach to Robust Control, Fig. 2 Typical examples of LMI region

all of its poles are in the LMI region D if and only if there is a positive-definite matrix $\mathbb{P}$ satisfying the LMI

$$L \otimes \mathbb{P} + M \otimes (A\mathbb{P}) + M^T \otimes (A\mathbb{P})^T < 0. \quad (29)$$

This forms the basis for the regional pole placement design.

For the disk region in Fig. 2a, the condition becomes

$$\begin{bmatrix} -r\mathbb{P} & c\mathbb{P} + A\mathbb{P} \\ c\mathbb{P} + (A\mathbb{P})^T & -r\mathbb{P} \end{bmatrix} < 0. \quad (30)$$

Meanwhile, for the sector region in Fig. 2b, the corresponding LMI is

$$\begin{bmatrix} (A\mathbb{P} + \mathbb{P}A^T) \sin \theta & (A\mathbb{P} - \mathbb{P}A^T) \cos \theta \\ -(A\mathbb{P} - \mathbb{P}A^T) \cos \theta & (A\mathbb{P} + \mathbb{P}A^T) \sin \theta \end{bmatrix} < 0. \quad (31)$$

Moreover, for a composite LMI region, such as the intersection of the disk and the sector, the pole placement is guaranteed by enforcing a common solution $\mathbb{P}$ to all the corresponding LMIs.

In the pole placement design, only the variable change method is applicable. For example, in the nominal closed-loop system Eq. (8), the pole placement condition is that the LMI

$$L \otimes \begin{bmatrix} X & I \\ I & Y \end{bmatrix} + \text{He} \left(M \otimes \begin{bmatrix} AX + BC & A + B\mathbb{D}C \\ \mathbb{A} & Y A + \mathbb{B}C \end{bmatrix} \right) < 0 \quad (32)$$

and Eq. (5) are solvable (Chilali and Gahinet 1996).

For systems with norm-bounded parameter uncertainty, a robust pole placement method is provided in Chilali et al. (1999).

Multi-objective Control

It is noted that all of the preceding control designs involve a positive-definite matrix $\mathbb{P}$. Therefore, a multi-objective control design is easily realized

by enforcing a common solution $\mathbb{P}$ to the corresponding matrix inequality conditions.

Gain-Scheduled Control

In practice, many nonlinear systems can be expressed as linear systems with state-dependent coefficients in form, which is known as the LPV (linear parameter-varying) form. For example, in the model of a robot arm $J\ddot{\theta} + mgl \sin \theta = u$, if we define a parameter as $p(t) = \sin \theta / \theta$, then it can be written as an LPV model $J\ddot{\theta}(t) + mglp(t)\theta(t) = u(t)$. In this class of systems, when the parameter $p(t)$ is available online and its range is finite, one may tune the controller parameters based on the information of $p(t)$, so as to achieve a higher performance. This is referred to as gain-scheduled control.

Consider the following affine model:

$$\dot{x} = A(p(t))x + B_1(p(t))d + B_2(p(t))u \quad (33)$$

$$z = C_1(p(t))x + D_{11}d + D_{12}u \quad (34)$$

$$y = C_2(p(t))x + D_{21}d \quad (35)$$

where $A(p) \sim C_2(p)$ are affine functions of the time-varying parameter vector $p(t)$, such as $A(p) = A_0 + \sum_{i=1}^q p_i(t)A_i$. The gain-scheduled control is to impose, on the coefficient matrices of the controller, the same affine structure about $p(t)$ such as $A_K(p) = A_{K0} + \sum_{i=1}^q p_i(t)A_{Ki}$.

To simplify the design, it is desirable that the coefficient matrices of the closed-loop system become affine functions of the parameter vector $p(t)$. This may be satisfied by restraining some of the matrices of the controller to constant ones. The easy-to-design structure of a gain-scheduled controller is summarized as follows:

- Both $B_2(p)$ and $C_2(p)$ depend on $p(t)$: (B_K, C_K) must be constant matrices besides $D_K = 0$.
- Constant (B_2, C_2) : All coefficient matrices of the controller can be affine functions of the parameter vector $p(t)$.

- Constant B_2 : (B_K, D_K) must be constant matrices.
- Constant C_2 : (C_K, D_K) must be constant matrices.

When the structure of the gain-scheduled controller is chosen as summarized above, the solvability conditions reduce to those at all vertices θ_i of the scheduling parameter vector $p(t)$. Further, a multi-objective is achieved by imposing a common solution $\mathbb{P}$ to all LMI conditions. Some concrete examples are illustrated below:

$\mathcal{H}_\infty$ Norm Spec: The conditions of Theorem 3 are satisfied at all vertices θ_j of the parameter vector $p(t)$.

$\mathcal{H}_2$ Norm Spec: The conditions of Theorem 1 are satisfied at all vertices θ_j of the parameter vector $p(t)$.

Regional Pole Placement: Eq. (32) is satisfied at all vertices θ_j of the parameter vector $p(t)$ and Eq. (5) holds.

Moreover, a different gain-scheduled method is proposed in Packard (1994) for parametric systems with norm-bounded uncertainty.

Summary and Future Direction

LMI approach is a very powerful method that can be applied to solve most of the robust control problems smartly and effectively. In particular, its capability of handling the multi-objective control problems is very attractive and proven useful in industrial applications.

Further study is needed in the following directions.

- New method of variable change is desired in order to deal with the robust performance design of parametric systems.
- Almost all robust performance designs are carried out based on sufficient conditions. It is very important to discover less conservative design methods.

Low-Power High-Gain Observers

Daniele Astolfi¹ and Lorenzo Marconi²
¹CNRS, LAGEPP UMR 5007, Villeurbanne, France
²C.A.SY. – DEI, University of Bologna, Bologna, Italy

Abstract

This entry deals with a class of nonlinear high-gain observers referred to as “low-power” due

to the fact that the high-gain parameter is powered only up to 2 regardless of the dimension of the observed system, on the contrary of conventional high-gain observers in which the high-gain parameter is powered up to the dimension of the observed system. This kind of observers preserves the main properties of conventional high-gain observers in terms of tunability of the speed of convergence and robustness to exogenous disturbances, by outperforming those in terms of numerical implementation and sensitivity to high-frequency measurement noise. The drawback of low-power high-gain observers over the conventional ones is given by the dimension of its dynamics that is larger.

Keywords

Nonlinear Observers · High-gain observers · Noise Sensitivity

Introduction

Observing the state of dynamical systems by processing available measurements is a problem ubiquitous in control. Output feedback stabilization (Atassi and Khalil 1999; Teel and Praly 1995), output regulation (Isidori 2017), and fault detection and isolation (Edwards et al. 2000) are only a few examples of research areas in which state observers play a key role. The problem of designing an observer becomes very challenging when the underlying dynamics are nonlinear and possibly affected by uncertainties, and a robust, possibly practical, estimation of the state is needed. In this regard a special role in the literature of robust nonlinear observers is played by the so-called high-gain observers (Khalil and Praly 2014). The adjective high-gain places emphasis on a feature of the observer whose structure distinguishes for a design parameter, referred to as the high-gain parameter, whose value is typically taken large to dominate the effect of uncertainties and to tune the speed of convergence of the estimation and the residual bound of the error that can be arbitrarily fixed.

A pretty common framework where high-gain observers are studied is the one of systems ful-

filling a *uniform observability assumption* (see Definition 1.2 in Gauthier and Kupka (2001)). This class of systems is described, possibly after a coordinates change, in the so-called canonical observability form (see Theorem 4.1 in Gauthier and Kupka (2001))

$$\begin{aligned}\dot{x}_1 &= x_2 \\ \dot{x}_2 &= x_3 \\ &\vdots \\ \dot{x}_{n-1} &= x_n \\ \dot{x}_n &= \varphi(x) \\ y &= x_1\end{aligned}\quad (1)$$

in which $x = \text{col}(x_1, \dots, x_n) \in \mathbb{R}^n$ is the state and $\varphi(\cdot)$ is nonlinear function. We observe that $x = \text{col}(y, \dot{y}, \dots, y^{(n-1)})$, namely, in this coordinate frame the state coincides with the output and its first $n-1$ time derivatives. The state is typically assumed to satisfy $x \in X$, in which X is a compact set of $\mathbb{R}^n$, whereas the function $\varphi(\cdot)$ is assumed to be *uniformly locally Lipschitz* in X , namely, there exists a constant $\bar{\varphi} > 0$ such that

$$\|\varphi(x') - \varphi(x'')\| \leq \bar{\varphi} \|x' - x''\| \quad \forall x', x'' \in X.$$

In this framework, conventional high-gain observers take the form

$$\begin{aligned}\dot{\hat{x}}_1 &= \hat{x}_2 + \ell c_1 (y - \hat{x}_1) \\ \dot{\hat{x}}_2 &= \hat{x}_3 + \ell^2 c_2 (y - \hat{x}_1) \\ &\vdots \\ \dot{\hat{x}}_{n-1} &= \hat{x}_n + \ell^{n-1} c_{n-1} (y - \hat{x}_1) \\ \dot{\hat{x}}_n &= \varphi_s(\hat{x}) + \ell^n c_n (y - \hat{x}_1)\end{aligned}\quad (2)$$

in which the c_i 's are chosen so that the polynomial $\lambda^n + c_n \lambda^{n-1} + \dots + c_2 \lambda + c_1$ is Hurwitz, $\varphi_s(\cdot)$ is a bounded function that agrees with $\varphi(\cdot)$ in X , and ℓ is the high-gain design parameter. It turns out (see Khalil and Praly (2014)) that there exists a $\ell^*(\bar{\varphi}) > 0$ such that for all $\ell \geq \ell^*$ the following estimate holds true

$$\|\hat{x}(t) - x(t)\| \leq \alpha \ell^{n-1} \exp(-\beta \ell t) \quad (3)$$

for all $\hat{x}(0) \in X$ and all the system trajectories $x(t) \in X$, in which (α, β) are positive constants (not dependent on ℓ). The previous bound shows that asymptotic estimation is achieved with an arbitrary fast convergence rate tuneable through the design high-gain parameter ℓ . The arbitrary fast convergence rate, though, is obtained at the expense of a “peaking phenomenon” leading to large estimation errors (proportional to ℓ^{n-1}) in the initial part of the transient. A clear drawback of this kind of observers when ℓ is picked large is also at implementation level due to the fact that numerical value of the coefficients scales up to ℓ^n .

High-gain observers can be shown also to be robust to disturbances entering anywhere in the chain of integrators of (1) and also affecting the measured output y . In particular, by adopting the observer (1) to an observed system of the form

$$\begin{aligned}\dot{x}_1 &= x_2 + d_1 \\ \dot{x}_2 &= x_3 + d_2 \\ &\vdots \\ \dot{x}_{n-1} &= x_n + d_{n-1} \\ \dot{x}_n &= \varphi(x) + d_n \\ y &= x_1 + v\end{aligned}\quad (4)$$

in which $d := \text{col}(d_1, \dots, d_n) \in D_d \subset \mathbb{R}^n$ and $v \in D_v \subset \mathbb{R}$ are bounded disturbances (with D_d and D_v compact sets of $\mathbb{R}^n$ and $\mathbb{R}$), it turns out that for a sufficiently large value of ℓ , the following estimate holds (see Astolfi and Marconi (2015))

$$\|\hat{x}(t) - x(t)\| \leq \max \left\{ \alpha \ell^{n-1} \exp(-\beta \ell t), \frac{\gamma}{\ell} \|\Gamma(\ell) d\|_\infty, \ell^{n-1} \theta \|v\|_\infty \right\} \quad (5)$$

for some positive constants $\alpha, \beta, \gamma, \theta$ (independent of ℓ) and with $\Gamma(\ell) := \text{diag}(\ell^{n-1}, \dots, \ell, 1)$. The form of $\Gamma(\ell)$, in particular, shows how the high-gain parameter affects the asymptotic gain of the disturbances on the estimation errors. As for disturbances entering in the first $n-1$ integrators, it turns out that ℓ affects the asymptotic gain in an unfavorable way, namely, the larger is the high-gain parameter, the larger is the effect of the disturbance d

on the asymptotic estimation error (with the exception of d_{n-1} in which the asymptotic gain is not affected by ℓ). As for the disturbance d_n , on the other hand, (5) shows that practical observation is achieved with an estimation error that can be steered to arbitrarily small values in arbitrarily small time by increasing the values of ℓ . Similarly, the measurements noise is amplified on the asymptotic estimation error of a quantity proportional to ℓ^{n-1} . The latter property, in turn, practically limits the convergence rate achievable from this kind of observers in noisy environments.

The Low-Power Observer Structure

The same asymptotic properties (5) guaranteed by the high-gain observer (2) could be obtained by a different observer structure, referred to as “low power,” in which the high-gain parameter is powered just up to the order two regardless of the dimension n of the observed system. The “low-power” high-gain observer is given by properly interconnecting $n - 1$ subsystems, each of dimension 2 and with state $(\hat{x}_{i1}, \hat{x}_{i2})$, $i = 1, \dots, n - 1$, according to the following structure proposed in Astolfi and Marconi (2015)

$$\begin{aligned}
 \dot{\hat{x}}_{11} &= \hat{x}_{12} + \ell c_{11}(y - \hat{x}_{11}) \\
 \dot{\hat{x}}_{12} &= \hat{x}_{22} + \ell^2 c_{12}(y - \hat{x}_{11}) \\
 &\vdots \\
 \dot{\hat{x}}_{i1} &= \hat{x}_{i2} + \ell c_{i1}(\hat{x}_{(i-1)2} - \hat{x}_{i1}) \\
 \dot{\hat{x}}_{i2} &= \hat{x}_{(i+1)2} + \ell^2 c_{i2}(\hat{x}_{(i-1)2} - \hat{x}_{i1}) \quad i = 2, \dots, n - 2 \\
 &\vdots \\
 \dot{\hat{x}}_{(n-1)1} &= \hat{x}_{(n-1)2} + \ell c_{(n-1)1}(\hat{x}_{(n-2)2} - \hat{x}_{(n-1)1}) \\
 \dot{\hat{x}}_{(n-1)2} &= \varphi_s(\hat{x}) + \ell^2 c_{(n-1)2}(\hat{x}_{(n-2)2} - \hat{x}_{(n-1)1})
 \end{aligned} \tag{6}$$

in which $\hat{x} = \text{col}(\hat{x}_{11}, \hat{x}_{21}, \dots, \hat{x}_{(n-1)1}, \hat{x}_{(n-2)2}) \in \mathbb{R}^n$, the $c_{i,j}$, $i = 1, 2$, $j = 1, \dots, n - 1$, are design coefficients, ℓ is the high-gain design parameter and $\varphi_s(\hat{x})$ is defined as in the canonical high-gain observer. A graphical sketch of the observer structure is shown in Fig. 1.

The intuition behind the observer structure is along the following lines. The first subsystem, with state $(\hat{x}_{11}, \hat{x}_{12})$, resembles the structure of a canonical high-gain observer aiming to estimate $(y, \dot{y})$. In this respect the term $\hat{x}_{22}$ acts as “consistency term” whose asymptotic value is expected to converge to $\ddot{y}$. This consistency term is provided by the state of the second subsystem, with state $(\hat{x}_{21}, \hat{x}_{22})$ still relying on a canonical high-gain structure and aiming to provide an estimation of $(\dot{y}, \ddot{y})$. The innovation term of this system, given by $\hat{x}_{12} - \hat{x}_{21}$, is in fact constructed by using the state variable $\hat{x}_{12}$ of the “previous” subsystem, acting as a “proxy” of $\dot{y}$, and the estimation of $\dot{y}$ provided by the state $\hat{x}_{21}$ of

the “actual” subsystem. Similar to the above, the consistency term is given by $\hat{x}_{32}$ provided by the “next” subsystem and expected to provide an estimation of $y^{(3)}$. This intuition continues all along the chain of the $(n - 1)$ subsystems of (6), with the state $(\hat{x}_{i1}, \hat{x}_{i2})$ of the generic i -th subsystem providing an estimation of $(y^{(i-1)}, y^{(i)})$ and with the innovation and the consistency terms constructed by using the state, respectively, of the “previous” and “next” subsystem. The fact that each subsystem has dimension 2 allows one to limit the power of the high-gain parameter to 2 regardless of the value of n , with the drawback of increasing the dimension of the overall observer to the dimension $2n - 2$. As the previous analysis reveals, a potential benefit of this redundancy is that the low-power observer provides a “double” estimate of the state $(y, \dot{y}, \dots, y^{(n-1)})$ of system (1). As a matter of fact, each variable $y^{(i)}$ is estimated twice, for $i = 1, \dots, n - 2$, by $\hat{x}_{i2}$ and $\hat{x}_{(i+1)2}$, with y and $y^{(n-1)}$ estimated

Low-Power High-Gain Observers, Fig. 1 Block diagram representation of the low-power high-gain observer (6)

once, respectively, by the state variables $\hat{x}_{11}$ and $\hat{x}_{(n-2)2}$. This fact justifies the introduction of a new vector

$$\hat{x}' := \text{col}(\hat{x}_{11}, \hat{x}_{12}, \hat{x}_{22}, \dots, \hat{x}_{(n-1)2}) \in \mathbb{R}^n$$

that, besides $\hat{x}$, represents an additional estimation of the state x .

Of course, the envisioned asymptotic properties of (6) rely on an appropriate choice of the coefficients $c_{i,j}$. With respect to canonical high-gain observers, this choice is slightly more complicated. In particular, define the following set of matrices

$$A_2 := \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix},$$

$$C_2 := (1, 0) \quad B_i := \text{col}(0, \dots, 0, 1) \in \mathbb{R}^i$$

$K_i := \text{col}(c_{i1}, c_{i2})$, and $E_i := A_2 - K_i C_2$, $i = 1, \dots, n-1$, and define recursively the matrices $M_i \in \mathbb{R}^{2i \times 2i}$, $i = 1, \dots, n-1$, as $M_1 := E_1$,

$$M_i := \begin{pmatrix} M_{i-1} & B_{2(i-1)} B_2^T \\ K_i B_{2(i-1)}^T & E_i \end{pmatrix},$$

$$i = 2, \dots, n-1$$

where $B_{2(i-1)}$ denotes the zero column vector of dimension $i-1$ with just a 1 in the last position. It turns out that the coefficients $c_{i,j}$ must be chosen such that the matrix M_{n-1} defined above is Hurwitz. As a matter of fact, in this case standard Lyapunov arguments (the same used also in the case of canonical high-gain observers) can be used to show that there exists a $\ell^*(\bar{\varphi})$ such that for all $\ell \geq \ell^*(\bar{\varphi})$ the state of the observer (6)

driven by the observed system (4) fulfills

$$\left\| \begin{pmatrix} \hat{x}(t) - x(t) \\ \hat{x}'(t) - x'(t) \end{pmatrix} \right\| \leq \max \left\{ \alpha \ell^{n-1} \exp(-\beta \ell t), \frac{\gamma}{\ell} \|\Gamma(\ell)d\|_\infty, \ell^{n-1} \theta \|v(t)\|_\infty \right\} \quad (7)$$

for some positive constants $(\alpha, \beta, \gamma, \theta)$ independent of ℓ and with $\Gamma(\ell)$ defined as before. Namely, the same nominal properties of the canonical high-gain observer, in terms of convergence speed and asymptotic properties in presence of disturbances, are preserved. As said, with respect to observer (2), the proposed structure (6) has larger dimension equal to $2n-2$, but the remarkable advantage of having the high-gain parameter ℓ powered just up to the order 2 regardless of the dimension n of the observed system.

We conclude the section by observing that a selection of the design parameters c_{ij} so that M_{n-1} is Hurwitz always exists. As a matter of fact, the Algorithm 1 presented next can be used (see Astolfi et al. 2016a).

It is worth remarking that the eigenvalues of M_{n-1} can be also arbitrarily assigned by following a more complex algorithm; see Lemma 1 in Astolfi and Marconi (2015).

Sensitivity to High-Frequency Noise

With reference to the sensitivity to measurement noise, it is worth noting that the bounds (5) and (7) refer to the so-called $\mathcal{L}_\infty$ gain, namely, characterizes the sensitivity to the class of *bounded* disturbances $v(t)$. It is a well-known

Algorithm 1 Computation of $c_{i,j}$ to obtain M_{n-1} Hurwitz

```

if  $i = 1$  then
    Select  $c_{11}, c_{12} > 0$ .
end if
for  $i = 2, \dots, n-1$  do
    Compute  $\gamma_i := \max_{\omega \in \mathbb{R}} \|G_i(j\omega)\|$  with  $G_i(s) := B_{2(i-1)}^\top (sI_{2(i-1)} - M_{i-1})^{-1} B_{2(i-1)}$ .
    Select  $c_{i1} := c_{(i-1)1}$ .
    Select any  $0 < c_{i2} < \frac{c_{i1}}{\gamma_i}$ .
end for

```

fact that measurement noises typically belong to a more restricted class of signals, namely, the one in which the harmonic content is confined at high frequency. In this respect, when the restricted class of *high-frequency* measurement noises is dealt with, the previous bound can be further refined by highlighting low-pass filtering properties of the observers (2) and (6), with the latter outperforming the former as detailed next. We consider, in particular, system (4) in which $d = 0$ and the measurement noise v is modelled as a quasi-periodic signal of the form

$$v(t) = \sum_{i=1}^{n_v} v_i^c \cos\left(\frac{\omega_i}{\varepsilon} t\right) + v_i^s \sin\left(\frac{\omega_i}{\varepsilon} t\right)$$

where n_v , v_i^c , v_i^s , ω_i are positive numbers and where $\varepsilon \in (0, 1)$ is a small number parametrizing the frequencies of the signal $v(t)$.

As for the canonical high-gain observer (2), it is possible to show (see Astolfi et al. 2016b) that the i -th estimation error fulfills the following bound

$$\limsup_{t \rightarrow \infty} \|\hat{x}_i(t) - x_i(t)\| \leq \varepsilon \mu \ell^i \|v\|_\infty$$

$$i = 1, \dots, n,$$

for all $0 < \varepsilon \leq \varepsilon^*(\ell)$, where $\varepsilon^*(\ell) > 0$ is positive constants depending on ℓ and μ is a positive constant independent of ℓ . This bound shows that once ℓ is fixed, the sensitivity of the estimation error to measurement noise decreases as ε takes smaller values, namely, as higher-frequency noise signals are considered, with an asymptotic gain proportional to ε . For linear

systems, this property immediately comes by frequency response arguments using the fact that the relative degree between the measurement noise v and the estimation error $\hat{x}_i - x_i$ for (4)–(2) is unitary for all $i = 1, \dots, n$.

Concerning the low-power high-gain observer (6), we observe that the relative degree between the “input” v and the i -th estimation error $\hat{x}_i - x_i$ is one for $i = 1$ (as for (2)) and then increases for higher values of i . More precisely, by defining $m := \lceil (n+1)/2 \rceil$ and considering a general case in which the function $\varphi(x)$ is affected by x_1 , the relative degree in question is i for $i = 1, \dots, m$ and $n - i + 2$ for $i = m+1, \dots, n$. As a consequence, it can be shown (see Astolfi et al. 2018) that the i -th estimation error associated with the low-power observer (6) fulfills the following bound

$$\limsup_{t \rightarrow \infty} \|\hat{x}_i(t) - x_i(t)\| \leq \varepsilon^i \mu \ell^{2i-1} \|v\|_\infty$$

for $i = 1, \dots, m$ and

$$\limsup_{t \rightarrow \infty} \|\hat{x}_i(t) - x_i(t)\| \leq \varepsilon^{n-i+2} \mu \ell \|v\|_\infty$$

for $i = m+1, \dots, n$, holding for $0 < \varepsilon \leq \varepsilon^*(\ell)$, where $\varepsilon^*(\ell) > 0$ is a constant depending on ℓ and $\mu > 0$ is a constant independent of ℓ . The previous bounds highlight the “low-pass” filter behaviors of the low-power high-gain observer (6) and moreover the remarkable feature of having an asymptotic gain between the measurement noise and the i -th error component that is proportional to ε powered at a value that increases as long as “higher” components of the errors are considered, as opposed to the standard case in which the asymptotic gain depends on ε regardless of the value of i . This fact, which is strongly related to the relative degree properties mentioned above, clearly shows that the new observer behaves better than the standard one as far as ε tends to zero, namely, as far as high-frequency noise is concerned. To better realize the improvements of the low-power high-gain observer over the standard one in relation to the sensitivity to high-frequency measurement noise, we recall the example reported in Astolfi and

Low-Power High-Gain Observers, Table 1

Normalized asymptotic errors in presence of measurement noise

Standard high-gain observer $\hat{x}$	Low-power high-gain observer $\hat{x}$	Low-power high-gain observer $\hat{x}'$
$\ \hat{x}_1 - x_1\ _a = 0.15$	$\ \hat{x}_{11} - x_1\ _a = 0.06$	$\ \hat{x}_{11} - x_1\ _a = 0.06$
$\ \hat{x}_2 - x_2\ _a = 8$	$\ \hat{x}_{21} - x_2\ _a = 0.2$	$\ \hat{x}_{12} - x_1\ _a = 3$
$\ \hat{x}_3 - x_3\ _a = 2 \cdot 10^2$	$\ \hat{x}_{31} - x_3\ _a = 0.2$	$\ \hat{x}_{22} - x_3\ _a = 3$
$\ \hat{x}_4 - x_4\ _a = 2.5 \cdot 10^3$	$\ \hat{x}_{41} - x_4\ _a = 0.1$	$\ \hat{x}_{32} - x_4\ _a = 2$
$\ \hat{x}_5 - x_5\ _a = 10^4$	$\ \hat{x}_{42} - x_5\ _a = 0.3$	$\ \hat{x}_{42} - x_5\ _a = 0.3$

Marconi (2015). Therein it is shown that the Van der Pol equation

$$\ddot{z} = -\rho^2 z + \sigma(1 - z^2)\dot{z}, \quad y = z + v(t),$$

with uncertain constant positive parameters ρ, σ can be immersed into a system of the form (1) with $n = 5$ with a known expression of φ that can be found in Astolfi and Marconi (2015). The performances of the two observers (2) and (6) have been tested with the design parameters chosen as indicated in Astolfi and Marconi (2015) and with high-frequency measurement noise $v(t) = a_N \sin(\omega_N t)$ with $a_N = 10^{-2}$ and $\omega_N = 10^3$. Table 1 shows the normalized asymptotic error magnitudes of the two observers, where the normalized asymptotic error for the i -th estimate is defined as $\|\hat{x}_i - x_i\|_a = \lim_{t \rightarrow \infty} \sup \|\hat{x}_i(t) - x_i(t)\|/a_N$. The numerical results show a remarkable improvement of the sensitivity to high-frequency measurement noise of the new observer with respect to the standard one confirming the analysis of this section. More examples can be also found in Astolfi et al. (2018).

Variants of the Low-Power Observer

Some variants of the low-power high-gain observer (6) are possible in order to deal with a more general class of systems or to improve performances. For instance, the low-power construction can be extended to the class of observed systems that, possibly after a change of coordinates, can be expressed in the following *generalized observability canonical form* (see Gauthier and Kupka 2001)

$$\begin{aligned} \dot{x}_1 &= f_1(\mathbf{x}_1, x_2) \\ &\vdots \\ \dot{x}_i &= f_i(\mathbf{x}_i, x_{i+1}) \\ &\vdots \\ \dot{x}_n &= f_n(\mathbf{x}_n) \\ y &= h(x_1) \end{aligned} \quad (8)$$

where $x = \text{col}(x_1, \dots, x_n) \in X$ is the state, $\mathbf{x}_i = \text{col}(x_1, \dots, x_i) \in \mathbb{R}^i$, and the functions f_i, h are Lipschitz functions in X fulfilling the following

$$\begin{aligned} \frac{\partial h(x_1)}{\partial x_1} &\neq 0, \quad \frac{\partial f_i(\mathbf{x}_i, x_{i+1})}{\partial x_{i+1}} \neq 0, \\ i &= 1, \dots, n-1 \end{aligned}$$

for all $x \in X$. This form clearly encompasses the one in (1). As shown in Wang et al. (2017), the low-power high-gain observer designed in these coordinates takes the form

$$\begin{aligned} \dot{\hat{x}}_{11} &= f_1(\hat{\mathbf{x}}_1, \hat{x}_{12}) + \ell c_{11}(y - h(\hat{x}_1)), \\ \dot{\hat{x}}_{12} &= f_2(\hat{\mathbf{x}}_2, \hat{x}_{22}) + \ell^2 c_{12}(y - h(\hat{x}_1)) \\ &\vdots \\ \dot{\hat{x}}_{i1} &= f_i(\hat{\mathbf{x}}_i, \hat{x}_{i2}) + \ell c_{i1}(\hat{x}_{(i-1)2} - \hat{x}_{i1}) \\ \dot{\hat{x}}_{i2} &= f_{i+1}(\hat{\mathbf{x}}_{i+1}, \hat{x}_{(i+1)2}) \\ &\quad + \ell^2 c_{i2}(\hat{x}_{(i-1)2} - \hat{x}_{i1}) \\ i &= 2, \dots, n-2 \\ &\vdots \\ \dot{\hat{x}}_{(n-1)1} &= f_{n-1}(\hat{\mathbf{x}}_{n-1}, \hat{x}_{(n-1)2}) \\ &\quad + \ell c_{(n-1)1}(\hat{x}_{(n-2)2} - \hat{x}_{(n-1)1}) \\ \dot{\hat{x}}_{(n-1)2} &= f_n(\hat{\mathbf{x}}_n) + \ell^2 c_{(n-1)2}(\hat{x}_{(n-2)2} - \hat{x}_{(n-1)1}) \end{aligned} \quad (9)$$

in which the estimate is given by $\hat{x} = \text{col}(\hat{x}_{11}, \hat{x}_{21}, \dots, \hat{x}_{(n-1)1}, \hat{x}_{(n-2)2})$, the variables

$\hat{\mathbf{x}}_i$ are used to denote the compact notation $\hat{\mathbf{x}}_i := \text{col}(\hat{x}_1, \dots, \hat{x}_i) \in \mathbb{R}^i$ and the $c_{i,j}$, $i = 1, 2$, $j = 1, \dots, n-1$ are positive coefficients to be properly chosen, according to Wang et al. (2017). Similar to the above, it can be proved that if ℓ is taken sufficiently large, then the state of the cascade (8)–(9) fulfills

$$\|\hat{x}(t) - x(t)\| \leq \alpha \ell^{n-1} \exp(-\beta \ell t),$$

for some positive α and β not dependent on ℓ . In presence of state disturbances d and measurement noise v , asymptotic bounds similar to the ones presented in sections “The Low-Power Observer Structure” and “Sensitivity to High-Frequency Noise” can be given.

$$\begin{aligned}
 \dot{\hat{x}}_{11} &= \hat{x}_{12} + \ell c_{11}(y - \hat{x}_{11}), \\
 \dot{\hat{x}}_{12} &= \text{sat}_{r_{i+2}}(\hat{x}_{22}) + \ell^2 c_{12}(y - \hat{x}_{11}) \\
 &\vdots \\
 \dot{\hat{x}}_{i1} &= \hat{x}_{i2} + \ell c_{i1}(\text{sat}_{r_i}(\hat{x}_{(i-1)2}) - \hat{x}_{i1}) \\
 \dot{\hat{x}}_{i2} &= \text{sat}_{r_{i+2}}(\hat{x}_{(i+1)2}) + \ell^2 c_{i2}(\text{sat}_{r_i}(\hat{x}_{(i-1)2}) - \hat{x}_{i1}) \quad i = 2, \dots, n-2 \\
 &\vdots \\
 \dot{\hat{x}}_{(n-1)1} &= \hat{x}_{(n-1)2} + \ell c_{(n-1)1}(\text{sat}_{r_{n-1}}(\hat{x}_{(n-2)2}) - \hat{x}_{(n-1)1}) \\
 \dot{\hat{x}}_{(n-1)2} &= \varphi_s(\hat{x}) + \ell^2 c_{(n-1)2}(\text{sat}_{r_{n-1}}(\hat{x}_{(n-2)2}) - \hat{x}_{(n-1)1}) \\
 \dot{\hat{x}}_{n1} &= \varphi_s(\hat{x}) + \ell c_{n1}(\text{sat}_{r_n}(\hat{x}_{(n-1)2}) - \hat{x}_{n1})
 \end{aligned} \tag{10}$$

where the state is now of dimension $2n-1$, the coefficients $c_{i,j}$ can be designed by following the procedure in the algorithm above with $c_{n1} > 0$ arbitrarily taken, and $\varphi_s(\cdot)$ is defined as before. By selecting as estimate $\hat{x} = \text{col}(\hat{x}_{11}, \hat{x}_{21}, \dots, \hat{x}_{(n-1)1}, \hat{x}_{n1})$, it turns out that for sufficiently large value of ℓ , the state of the cascade (1)–(10) fulfills the following asymptotic bound

$$\|\hat{x}(t) - x(t)\| \leq \min \left\{ \alpha \ell^{n-1} \exp(-\beta \ell t), \delta \right\} \tag{11}$$

where (α, β, δ) are positive constants independent of ℓ . The bound (11) guarantees that the estimation error $\|\hat{x} - x\|$ is bounded, for all time, by a constant which is independent of ℓ , preventing therefore the peaking phenomenon.

A further interesting extension of the low-power observer is the one proposed in Astolfi et al. (2018) in order to eliminate the peaking phenomenon associated with the high-gain structures, both standard and low-power, presented before. In particular, consider the canonical observability form (1), define $r_i > 0$ as

$$r_i := \max_{x \in X} |x_i| \quad i = 1, \dots, n,$$

and let $\text{sat}_{r_i}(\cdot)$ be the piecewise linear saturation function with saturation level r_i , $i = 1, \dots, n$. Then, the low-power peaking-free observer takes the following form (Astolfi et al. 2018)

Furthermore, the asymptotic properties of the estimation error $\|\hat{x} - x\|$ of the low-power high-gain observer (7) are retained.

Summary

In this entry we presented low-power high-gain observers as potential effective alternative to conventional high-gain solutions. With respect to the latter, the low-power version has the advantage of having the high-gain parameter just powered up to the order to 2 regardless of the dimension of the observed system and of having substantial better performances in terms of sensitivity to high-frequency measurement noises. The low-power solution preserves all the important features of conventional high-gain observers that

make them an important tool in many control contexts. Application contexts of the low-power can be found in Astolfi et al. (2017) where output regulation and output feedback stabilization problems are addressed. It is worth also observing that the low-power idea can be extended to the problem of recursive stabilization through backstepping in order to limit the power of the stabilizing high-gain parameter as shown in Astolfi et al. (2017).

Lyapunov Methods in Power System Stability

Hsiao-Dong Chiang

School of Electrical and Computer Engineering,
Cornell University, Ithaca, NY, USA

Abstract

Energy functions, an extension of the Lyapunov functions, have been practically used in electric power systems for several applications. A comprehensive energy function theory for general nonlinear autonomous dynamical systems, along with its applications to electric power systems, will be summarized in this entry. Several schemes for constructing numerical energy functions for power system transient stability models expressed as a set of general differential-algebraic equations are presented. A practical application of energy functions for direct stability assessment of power system transient stability is also presented.

Lyapunov functions · Energy functions · Direct stability analysis · Electric power systems · Large-scale nonlinear systems

Introduction

Energy functions, an extension of the Lyapunov functions, have been practically used in electric power systems for several applications. A comprehensive energy function theory for general nonlinear autonomous dynamical systems along with its applications to electric power systems will be summarized in this entry.

We consider a general nonlinear autonomous dynamical system described by the following equation:

$$\dot{x}(t) = f(x(t)) \quad (1)$$

We say a function $V : R^n \rightarrow R$ is an energy function for the system (1) if the following three conditions are satisfied (Chiang et al. 1987):

- (E1): The derivative of the energy function $V(x)$ along any system trajectory $x(t)$ is nonpositive, i.e., $\dot{V}(x(t)) \leq 0$.
- (E2): If $x(t)$ is a nontrivial trajectory (i.e., $x(t)$ is not an equilibrium point), then along the nontrivial trajectory $x(t)$, the set $\{t \in R : V(x(t)) = 0\}$ has measure zero in R .
- (E3): That a trajectory $x(t)$ has a bounded value of $V(x(t))$ for $t \in R^+$ implies that the trajectory $x(t)$ is also bounded.

Condition (E1) indicates that the value of an energy function is nonincreasing along its trajectory, but does not imply that the energy function is strictly decreasing along any trajectory. Conditions (E1) and (E2) imply that the energy function is strictly decreasing along any system trajectory. Property (E3) states that the energy function is a proper map along any system trajectory but need not be a proper map for the entire state space. Obviously, an energy function may not be a Lyapunov function.

The task of constructing an energy function for a (post-fault) transient stability model is essential to direct stability analysis of power systems. The role of the energy function is to make feasible a direct determination of whether a given point (such as the initial point of a post-fault power system) lies inside the stability region of a post-fault SEP without performing numerical integration. It has been shown that a general (analytical) energy

function for power systems with losses does not exist (Chiang 1989). One key implication is that any general procedure attempting to construct an energy function for a lossy power system transient stability model must include a step that checks for the existence of an energy function. This step essentially plays the same role as the Lyapunov equation in determining the stability of an equilibrium point.

Several schemes for constructing numerical energy functions for power system transient stability models expressed as a set of general differential-algebraic equations (DAEs) are available (Chu and Chiang 1999, 2005). An energy function for an AC/DC power system represented by a structure-preserving model considering detailed DC dynamics was developed in Jiang and Chiang (2013). The function was theoretically shown to satisfy the required conditions (E1) and (E2). The monotonic decreasing property of the energy function was numerically demonstrated in several examples.

Energy Function Theory

In general, the dynamical behaviors of trajectories of general nonlinear systems can be very complicated. The asymptotical behaviors (i.e., the ω -limit set) of trajectories can be quasiperiodic trajectories or chaotic trajectories. However, as shown below, every trajectory of system (1) having an energy function has only two modes of behaviors: its trajectory either converges to an equilibrium point or goes to infinity (becomes unbounded) as time increases. This result is explained in the following theorem.

Theorem 1 (Global Behavior of Trajectories)

If there exists a function satisfying condition (E1) and condition (E2) of the energy function for system (1), then every bounded trajectory of system (1) converges to one of the equilibrium points.

Theorem 1 asserts that there does not exist any limit cycle (oscillatory behavior) or bounded complicated behavior such as an almost periodic trajectory, chaotic motion, etc. in the sys-

tem. We next show a sharper result, asserting that every trajectory on the stability boundary must converge to one of the unstable equilibrium points (UEPs) on the stability boundary. Recall that for a hyperbolic equilibrium point, it is an (asymptotically) *stable equilibrium point* if all the eigenvalues of its corresponding Jacobian have negative real parts; otherwise, it is an *unstable equilibrium point*. Let $\hat{x}$ be a hyperbolic equilibrium point. Its stable and unstable manifolds, $W^s(\hat{x})$ and $W^u(\hat{x})$, are well defined. There are many physical systems such as electric power systems containing multiple stable equilibrium points. A useful concept for these kinds of systems is that of the *stability region* (also called the *region of attraction*). The stability region of a stable equilibrium point x_s is defined as $A(x_s) := \{x \in R^n : \lim_{t \rightarrow \infty} \Phi_t = x_s\}$.

Theorem 2 (Trajectories on the Stability Boundary Chiang et al. 1987) *If there exists an energy function for system (1), then every trajectory on the stability boundary $\partial A(x_s)$ converges to one of the equilibrium points on the stability boundary.*

The significance of this theorem is that it offers an effective way to characterize the stability boundary. In fact, Theorem 2 asserts that the stability boundary $\partial A(x_s)$ is contained in the union of stable manifolds of the UEPs on the stability boundary, i.e.,

$$\partial A(x_s) \subseteq \bigcup_{x_i \in \{E \cap \partial A(x_s)\}} W^s(x_i)$$

The above two theorems give interesting results on the structure of the equilibrium points on the stability boundary. They lead to the development of a controlling UEP method for direct assessment of power system stability (Chiang et al. 1987; Chiang 2011). Moreover, Theorem 2 presents a necessary condition for the existence of certain types of equilibrium points on a *bounded* stability boundary.

Theorem 3 (Unbounded Stability Region Chiang et al. 1987) *If there exists an energy function for system (1) which has an asymptotically*

stable equilibrium point x_s and if $\partial A(x_s)$ contains no source, then the stability region $A(x_s)$ is unbounded.

A direct application of Theorem 3 is that the stability region of a power system stability model which admits an energy function is unbounded.

Optimally Estimating the Stability Region Using Energy Functions

In this section, we focus on how to optimally determine the critical level value of an energy function for estimating the stability boundary $\partial A(x_s)$. We consider the following set:

$$S_v(k) = \{x \in R^n : V(x) < k\} \quad (2)$$

where $V(\bullet) : R^n \rightarrow R$ is an energy function. We shall call the boundary of set (2) $\partial S(k) := \{x \in R^n : V(x) = k\}$ the level set (or constant energy surface) and k the level value. Generally speaking, this set $S(k)$ can be very complicated with several connected components, even for the two-dimensional case. We use the notation $S_k(x_s)$ to denote the only component of the several disjoint connected components of S_k that contains the stable equilibrium point x_s .

Theorem 4 (Optimal Estimation) *Consider the nonlinear system (1) which has an energy function $V(x)$. Let x_s be an asymptotically stable equilibrium point whose stability region $A(x_s)$ is not dense in R^n . Let E_1 be the set of type one equilibrium points and $\hat{c} = \min_{x_i \in \partial A(x_s) \cap E_1} V(x_i)$. Then,*

1. $S_{\hat{c}}(x_s) \subset A(x_s)$
2. *The set $\{S_b(x_s) \cap \bar{A}^c(x_s)\}$ is nonempty for any number $b > \hat{c}$.*

This theorem leads to an optimal estimation of the stability region $A(x_s)$ via an energy function $V(\cdot)$ (Chiang 1989). For the purpose of illustration, we consider the following simple example:

$$\begin{aligned}\dot{x}_1 &= -\sin x_1 - 0.5 \sin(x_1 - x_2) + 0.01 \\ \dot{x}_2 &= -0.5 \sin x_2 - 0.5 \sin(x_2 - x_1) + 0.05\end{aligned}\quad (3)$$

It is easy to show that the following function is an energy function for system (3):

$$\begin{aligned}V(x_1, x_2) &= -2 \cos x_1 - \cos x_2 - \cos(x_1 - x_2) \\ &\quad - 0.02x_1 - 0.1x_2\end{aligned}\quad (4)$$

The point $x_s(x_1^s, x_2^s) = (0.02801, 0.06403)$ is the stable equilibrium point whose stability region is to be estimated. Applying the optimal scheme to system (3), we have the critical level value of 0.31329. Curve A in Fig. 1 is the exact stability boundary $\partial A(x_s)$, while Curve B is the stability boundary estimated by the connected component (containing the s.e.p. x_s) of the constant energy surface. It can be seen that the critical level value, 0.31329, is indeed the optimal value.

Application of Energy Functions to Electric Power Grids

After decades of research and development in the energy-function-based direct methods and the time-domain simulation approach, it has become clear that the capabilities of direct methods and that of the time-domain approach complement each other. The current direction of development is to include appropriate direct methods and time-domain simulation programs within the body of overall power system stability simulation programs (Chiang et al. 1995; Chiang 1999, 2011; Fouad and Vittal 1991; Sauer and Pai 1998). In this development, the BCU direct method performs the function of fast screening and ranking of a large contingency list to identify unstable and critical contingencies and screen out stable contingencies which represent the majority ones. Only the identified unstable or potentially unstable contingencies are sent to the time-domain simulation program for detailed simulation/analysis.

The PJM Interconnection has successfully designed and implemented a Transient Stability

Lyapunov Methods in Power System Stability, Fig. 1 Curve A is the exact stability boundary $\partial A(x_s)$ of system (5), while Curve B is the stability boundary estimated by the constant energy surface (with a level value of 0.31329) of the energy function

Analysis & Control (TSA&C) system at its energy management system (EMS). The EMS provides a real-time snapshot including power flow case data from the state estimator, dynamic data, and a contingency list to the TSA&C application. For each real-time snapshot, TSA&C performed a transient stability assessment against the list of 3000 contingencies and calculated the stability limits on key transfer interfaces (Chiang et al. 2013). TEPCO-BCU was selected as the leading fast screening tool for improving the performance of the PJM TSA system (Tong et al. 2010). The TEPCO-BCU software was evaluated in the PJM TSA Test System environment. The evaluation period was chosen to include the scheduled outage season and the summer peak load season.

During this evaluation period, both the PJM TSA software and the TEPCO-BCU software were run periodically in parallel, every 15 min in the PJM TSA Test System environment. The goal was to evaluate TEPCO-BCU in a real-time environment as a transient stability analysis screening tool. The total number of contingencies involved in this evaluation is about 5.3 million. It is the ability to perform dynamic contingency screening on a large number of contingencies and filter out a much smaller number of contingencies

Lyapunov Methods in Power System Stability, Table 1 Overall performance of TEPCO-BCU for online contingency screening

Reliability measure	Screening measurement	Computation speed	Online computation
100%	92% to 99.5%	1.3 s	Yes

requiring further analysis that would make online TSA feasible.

A summary of the overall performance of TEPCO-BCU indicates that TEPCO-BCU is a fast and accurate screening tool for online transient stability analysis of large-scale power systems. Of the 5.3 million contingencies, all the unstable contingencies verified by detailed time domain simulation were classified by TEPCO-BCU as unstable. These unstable contingencies exhibit first-swing instability as well as multi-swing instability. The percentage of screening for stable contingencies is shown in Table 1. For a total of 5.29 million contingencies, on average, TEPCO-BCU consumes about 1.3556 s for the stability assessment of each contingency. Depending on the loading conditions and network topologies, the screening rate ranges from 92% to 99.5%, meaning the TEPCO-BCU quickly screens out, for every 100 stable contingencies, between 92 contingencies and 99.5 contingencies which are definitely stable.

This evaluation study confirms the author’s belief that theory-based solution methods can lead to practical applications in large-scale non-linear systems.

Summary and Future Directions

After decades of research and development in energy-function-based direct methods, it has become clear that the capabilities of the controlling UEP method and those of the time-domain simulation approach complement each other. The current direction of development is to incorporate the BCU-based controlling UEP method and time-domain simulation programs into the body of overall online transient stability assessments (online TSA). Online TSA has been

designed to provide power system operators with critical information, including the following:

- (i) Assessment of the transient stability of a power system subject to a list of contingencies.
- (ii) Available (power) transfer limits at key interfaces subject to transient stability constraints.

With the proliferation of renewable energy resources in the electric power grid, it becomes clear that online TSA needs to include the uncertainties brought by renewable energy into the overall assessment. The uncertainties of renewable energy can be expressed as a set of scenarios and put into a list of renewable contingencies (i.e., uncertainties). Hence, item (i) needs to extend into the following:

- (i) Assessment of the transient stability of a power system subject to a list of (network) contingencies and a list of renewable contingencies.

Lyapunov's Stability Theory

Hassan K. Khalil

Department of Electrical and Computer Engineering, Michigan State University, East Lansing, MI, USA

Abstract

Lyapunov's theory for characterizing and studying the stability of equilibrium points is presented for time-invariant and time-varying systems modeled by ordinary differential equations.

Keywords

Asymptotic stability · Equilibrium point · Exponential stability · Global asymptotic stability · Hurwitz matrix · Invariance principle · Linearization · Lipschitz condition · Lyapunov function · Lyapunov surface · Negative (semi-) definite function · Perturbed system · Positive (semi-) definite function · Region of attraction · Stability · Time-invariant system · Time-varying system

Introduction

Stability theory plays a central role in systems theory and engineering. For systems represented by state models, stability is characterized by studying the asymptotic behavior of the state variables near steady-state solutions, like equilibrium points or periodic orbits. In this article, Lyapunov's method for determining the stability of equilibrium points is introduced. The attractive features of the method include a solid theoretical foundation, the ability to conclude stability without knowledge of the solution (no extensive simulation effort), and an analytical framework that makes it possible to study the effect of model perturbations and design feedback control. Its main drawback is the need to search for an auxiliary function that satisfies certain conditions.

Stability of Equilibrium Points

We consider a nonlinear system represented by the state model

$$\dot{x} = f(x) \quad (1)$$

where the n -dimensional **locally Lipschitz** function $f(x)$ is defined for all x in a domain $D \subset R^n$. A function $f(x)$ is locally Lipschitz at a point x_0 if it satisfies the **Lipschitz condition** $\|f(x) - f(y)\| \leq L\|x - y\|$ for all x, y in some neighborhood of x_0 , where L is a positive constant and $\|x\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}$. The Lipschitz condition guarantees that Eq. (1) has a unique solution for given initial state $x(0)$. Suppose $\bar{x} \in D$ is an **equilibrium point** of Eq. (1); that is, $f(\bar{x}) = 0$. Whenever the state of the system starts at $\bar{x}$, it will remain at $\bar{x}$ for all future time. Our goal is to characterize and study the stability of $\bar{x}$. For convenience, we take $\bar{x} = 0$. There is no loss of generality in doing so because any equilibrium point $\bar{x}$ can be shifted to the origin via the change of variables $y = x - \bar{x}$. Therefore, we shall always assume that $f(0) = 0$ and study stability of the origin $x = 0$.

The equilibrium point $x = 0$ of Eq. (1) is **stable** if for each $\varepsilon > 0$, there is $\delta = \delta(\varepsilon) > 0$ such that $\|x(0)\| < \delta$ implies that $\|x(t)\| < \varepsilon$, for all $t \geq 0$. It is **asymptotically stable** if it is stable and δ can be chosen such that $\|x(0)\| < \delta$ implies that $x(t)$ converges to the origin as t tends to infinity. When the origin is asymptotically stable, the **region of attraction** (also called region of asymptotic stability, domain of attraction, or basin) is defined as the set of all points x such that the solution of Eq. (1) that starts from x at time $t = 0$ approaches the origin as t tends to ∞ . When the region of attraction is the whole space, we say that the origin is **globally asymptotically stable**. A stronger form of asymptotic stability arises when there exist positive constants c , k , and λ such that the solutions of Eq. (1) satisfy the inequality

$$\|x(t)\| \leq k\|x(0)\|e^{-\lambda t}, \quad \forall t \geq 0 \quad (2)$$

for all $\|x(0)\| < c$. In this case, the equilibrium point $x = 0$ is said to be **exponentially stable**. It is said to be **globally exponentially stable** if the inequality is satisfied for any initial state $x(0)$.

Linear Systems

For the linear time-invariant system

$$\dot{x} = Ax \quad (3)$$

the stability properties of the origin can be determined by the location of the eigenvalues of A . The origin is stable if and only if all the eigenvalues of A satisfy $\text{Re}[\lambda_i] \leq 0$ and for every eigenvalue with $\text{Re}[\lambda_i] = 0$ and algebraic multiplicity $q_i \geq 2$, $\text{rank}(A - \lambda_i I) = n - q_i$, where n is the dimension of x and q_i is the multiplicity of λ_i as a zero of $\det(\lambda I - A)$. The origin is globally exponentially stable if and only if all eigenvalues of A have negative real parts; that is, A is a **Hurwitz matrix**. For linear systems, the notions of asymptotic and exponential stability are equivalent because the solution is formed of exponential modes. Moreover, due to linearity, if the origin is exponentially stable, then the inequality of Eq. (2) will hold for all initial states.

Linearization

Suppose the function $f(x)$ of Eq. (1) is continuously differentiable in a domain D containing the origin. The Jacobian matrix $[\partial f / \partial x]$ is an $n \times n$ matrix whose (i, j) element is $\partial f_i / \partial x_j$. Let A be the Jacobian matrix evaluated at the origin $x = 0$. It can be shown that

$$f(x) = [A + G(x)]x, \quad \text{where } \lim_{x \rightarrow 0} G(x) = 0$$

This suggests that in a small neighborhood of the origin we can approximate the nonlinear system $\dot{x} = f(x)$ by its linearization about the origin $\dot{x} = Ax$. Indeed, we can draw conclusions about the stability of the origin as an equilibrium point for the nonlinear system by examining the eigenvalues of A . The origin of Eq. (1) is exponentially stable if and only if A is Hurwitz. It is unstable if $\text{Re}[\lambda_i] > 0$ for one or more of the eigenvalues of A . If $\text{Re}[\lambda_i] \leq 0$ for all i , with $\text{Re}[\lambda_i] = 0$ for

some i , we cannot draw a conclusion about the stability of the origin of Eq. (1).

Lyapunov's Method

Let $V(x)$ be a continuously differentiable scalar function defined in a domain $D \subset R^n$ that contains the origin. The function $V(x)$ is said to be **positive definite** if $V(0) = 0$ and $V(x) > 0$ for $x \neq 0$. It is said to be **positive semidefinite** if $V(x) \geq 0$ for all x . A function $V(x)$ is said to be **negative definite** or **negative semidefinite** if $-V(x)$ is positive definite or positive semidefinite, respectively. The derivative of V along the trajectories of Eq. (1) is given by

$$\dot{V}(x) = \sum_{i=1}^n \frac{\partial V}{\partial x_i} \dot{x}_i = \frac{\partial V}{\partial x} f(x)$$

where $[\partial V / \partial x]$ is a row vector whose i th component is $\partial V / \partial x_i$.

Lyapunov's stability theorem states that *the origin is stable if there is a continuously differentiable positive definite function $V(x)$ so that $\dot{V}(x)$ is negative semidefinite, and it is asymptotically stable if $\dot{V}(x)$ is negative definite*. A function $V(x)$ satisfying the conditions for stability is called a **Lyapunov function**. The surface $V(x) = c$, for some $c > 0$, is called a **Lyapunov surface** or a level surface.

When $\dot{V}(x)$ is only negative semidefinite, we may still conclude asymptotic stability of the origin if we can show that no solution can stay identically in the set $\{\dot{V}(x) = 0\}$, other than the zero solution $x(t) \equiv 0$. Under this condition, $V(x(t))$ must decrease toward 0, and consequently $x(t)$ converges to zero as t tends to infinity. This extension of the basic theorem is known as **the invariance principle**.

Lyapunov functions can be used to estimate the region of attraction of an asymptotically stable origin, that is, to find sets contained in the region of attraction. Let $V(x)$ be a Lyapunov function that satisfies the conditions of asymptotic stability over a domain D . For a positive constant c , let Ω_c be the component of $\{V(x) \leq$

$c\}$ that contains the origin in its interior. The properties of V guarantee that, by choosing c small enough, Ω_c will be bounded and contained in D . Then, every trajectory starting in Ω_c remains in Ω_c and approaches the origin as $t \rightarrow \infty$. Thus, Ω_c is an estimate of the region of attraction. If $D = R^n$ and $V(x)$ is radially unbounded, that is, $\|x\| \rightarrow \infty$ implies that $V(x) \rightarrow \infty$, then any point $x \in R^n$ can be included in a bounded set Ω_c by choosing c large enough. Therefore, *the origin is globally asymptotically stable if there is a continuously differentiable, radially unbounded function $V(x)$ such that for all $x \in R^n$, $V(x)$ is positive definite and $\dot{V}(x)$ is either negative definite or negative semidefinite but no solution can stay identically in the set $\{\dot{V}(x) = 0\}$ other than the zero solution $x(t) \equiv 0$* .

Time-Varying Systems

Equation (1) is time-invariant because f does not depend on t . The more general time-varying system is represented by

$$\dot{x} = f(t, x) \quad (4)$$

In this case, we may allow the Lyapunov function candidate V to depend on t . Let $V(t, x)$ be a continuously differentiable function defined for all $t \geq 0$ and $x \in D$. The derivative of V along the trajectories of Eq. (4) is given by

$$\dot{V}(t, x) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(t, x)$$

If there are positive definite functions $W_1(x)$, $W_2(x)$, and $W_3(x)$ such that

$$W_1(x) \leq V(t, x) \leq W_2(x) \quad (5)$$

$$\dot{V}(t, x) \leq -W_3(x) \quad (6)$$

for all $t \geq 0$ and all $x \in D$, then the origin is uniformly asymptotically stable, where "uniformly" indicates that the ε - δ definition of stability and the convergence of $x(t)$ to zero are independent of the initial time t_0 . Such uniformity annotation is not needed with time-invariant systems since the solution of a time-invariant state equation starting at time t_0 depends only on the difference

$t - t_0$, which is not the case for time-varying systems. If the inequalities of Eqs. (5) and (6) hold globally and $W_1(x)$ is radially unbounded, then the origin is globally uniformly asymptotically stable. If $W_1(x) = k_1\|x\|^a$, $W_2(x) = k_2\|x\|^a$, and $W_3(x) = k_3\|x\|^a$ for some positive constants k_1, k_2, k_3 , and a , then the origin is exponentially stable.

Perturbed Systems

Consider the system

$$\dot{x} = f(t, x) + g(t, x) \quad (7)$$

where f and g are continuous in t and locally Lipschitz in x , for all $t \geq 0$ and $x \in D$, in which $D \subset \mathbb{R}^n$ is a domain that contains the origin $x = 0$. Suppose $f(t, 0) = 0$ and $g(t, 0) = 0$ so that the origin is an equilibrium point of Eq. (7). We think of the system (7) as a perturbation of the nominal system (4). The perturbation term $g(t, x)$ could result from modeling errors, uncertainties, or disturbances. In a typical situation, we do not know $g(t, x)$, but we know some information about it, like knowing an upper bound on $\|g(t, x)\|$. Suppose the nominal system has an exponentially stable equilibrium point at the origin, what can we say about the stability of the origin as an equilibrium point of the perturbed system? A natural approach to address this question is to use a Lyapunov function for the nominal system as a Lyapunov function candidate for the perturbed system.

Let $V(t, x)$ be a Lyapunov function that satisfies

$$c_1\|x\|^2 \leq V(t, x) \leq c_2\|x\|^2 \quad (8)$$

$$\frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(t, x) \leq -c_3\|x\|^2 \quad (9)$$

$$\left\| \frac{\partial V}{\partial x} \right\| \leq c_4\|x\| \quad (10)$$

for all $x \in D$ for some positive constants c_1, c_2, c_3 , and c_4 . Suppose the perturbation term $g(t, x)$ satisfies the linear growth bound

$$\|g(t, x)\| \leq \gamma\|x\|, \quad \forall t \geq 0, \quad \forall x \in D \quad (11)$$

where γ is a nonnegative constant. We use V as a Lyapunov function candidate to investigate the stability of the origin as an equilibrium point for the perturbed system. The derivative of V along the trajectories of Eq. (7) is given by

$$\dot{V}(t, x) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(t, x) + \frac{\partial V}{\partial x} g(t, x)$$

The first two terms on the right-hand side are the derivative of $V(t, x)$ along the trajectories of the nominal system, which is negative definite and satisfies the inequality of Eq. (9). The third term, $[\partial V / \partial x]g$, is the effect of the perturbation. Using Eqs. (9) through (11), we obtain

$$\begin{aligned} \dot{V}(t, x) &\leq -c_3\|x\|^2 + \left\| \frac{\partial V}{\partial x} \right\| \|g(t, x)\| \\ &\leq -c_3\|x\|^2 + c_4\gamma\|x\|^2 \end{aligned}$$

If $\gamma < c_3/c_4$, then

$$\leq -(c_3 - \gamma c_4)\|x\|^2, \quad (c_3 - \gamma c_4) > 0$$

which shows that the origin is an exponentially stable equilibrium point of the perturbed system (7).

Summary

Lyapunov's method is a powerful tool for studying the stability of equilibrium points. However, there are two drawbacks of the method. First, there is no systematic procedure for finding Lyapunov functions. Second, the conditions of the theory are only sufficient; they are not necessary. Failure of a Lyapunov function candidate to satisfy the conditions for stability or asymptotic stability does not mean that the origin is not stable or asymptotically stable. These drawbacks have been mitigated by a long history of using the method in the analysis and design of engineering systems, where various techniques for finding Lyapunov functions for specific systems have been determined.

Abstract

Markov chains refer to stochastic processes whose states change according to transition probabilities determined only by the states of the previous time step. They have been crucial for modeling large-scale systems with random behavior in various fields such as control, communications, biology, optimization, and economics. In this entry, we focus on their recent application to the area of search engines, namely, the PageRank algorithm employed at Google, which provides a measure of importance for each page in the web. We present several researches carried out with control theoretic tools such as aggregation, distributed randomized algorithms, and PageRank optimization. Due to the large size of the web, computational issues are the underlying motivation of these studies.

Introduction

For various real-world large-scale dynamical systems, reasonable models describing highly complex behaviors can be expressed as stochastic systems, and one of the most well-studied classes of such systems is that of Markov chains. A characteristic feature of Markov chains is that their behavior does not carry any memory. That is, the current state of a chain is completely determined by the state of the previous time step and not at all on the states prior to that step (Kumar and Varaiya 1986; Norris 1997).

Recently, Markov chains have gained renewed interest due to the extremely successful applications in the area of web search. The search engine of Google has been employing an algorithm known as PageRank to assist the ranking of search results. This algorithm models the network of web pages as a Markov chain whose states represent the pages that web surfers with various interests visit in a random fashion. The objective is to find an order among the pages according to their popularity and importance, and this is done by focusing on the structure of hyperlinks among pages.

[†]Roberto Tempo passed away before publication of this work was completed.

In this entry, we first provide a brief overview on the basics of Markov chains and then introduce the problem of PageRank computation. We proceed to provide further discussions on control theoretic approaches dealing with PageRank problems. The topics covered include aggregated Markov chains, distributed randomized algorithms, and Markov decision problems for link optimization.

Markov Chains

In the simplest form, a Markov chain takes its states in a finite state space with transitions in the discrete-time domain. The transition from one state to another is characterized completely by the underlying probability distribution.

Let $\mathcal{X}$ be a finite set given by $\mathcal{X} := \{1, 2, \dots, n\}$, which is called the state space. Consider a stochastic process $\{X_k\}_{k=0}^{\infty}$ taking values on this set $\mathcal{X}$. Such a process is called a Markov chain if it exhibits the following Markov property:

$$\text{Prob}\{X_{k+1} = j | X_k = i_k, X_{k-1} = i_{k-1}, \dots, X_0 = i_0\} = \text{Prob}\{X_{k+1} = j | X_k = i_k\},$$

where $\text{Prob}\{\cdot | \cdot\}$ denotes the conditional probability and $k \in \mathbb{Z}_+$. That is, the state at the next time step depends only on the current state and not those of previous times.

Here, we consider the homogeneous case where the transition probability is constant over time. Thus, we have for each pair $i, j \in \mathcal{X}$, the probability that the chain goes from state j to state i at time k expressed as

$$p_{ij} := \text{Prob}\{X_k = i | X_{k-1} = j\}, \quad k \in \mathbb{Z}_+.$$

In the matrix form, $P := (p_{ij})$ is called the transition probability matrix of the chain. It is obvious that all entries of P are nonnegative, and for each j , the entries of the j th column of P sum up to 1, i.e., $\sum_{i=1}^n p_{ij} = 1$ for $j \in \mathcal{X}$. In this respect, the matrix P is (column) stochastic (Horn and Johnson 1985).

In this entry, we assume that the Markov chain is ergodic, meaning that for any pair of states, the chain can make a transition from one to the other over time. In this case, the chain and the matrix P are called irreducible. This property is known to imply that P has a simple eigenvalue of 1. Thus, there exists a unique steady-state probability distribution $\pi \in \mathbb{R}^n$ given by

$$\pi = P\pi, \quad \mathbf{1}^T \pi = 1, \quad \pi_i > 0, \quad \forall i \in \mathcal{X},$$

where $\mathbf{1} \in \mathbb{R}^n$ denotes a vector with entries one. Note that in this distribution π , all entries are positive.

Ranking in Search Engines: PageRank Algorithm

At Google, PageRank is used to quantify the importance of each web page based on the hyperlink structure of the web (Brin and Page 1998; Ishii and Tempo 2014; Langville and Meyer 2006). A page is considered important if (i) many pages have links pointing to the page, (ii) such pages having links are important ones, and (iii) the numbers of links that such pages have are limited. Intuitively, these requirements are reasonable. For a web page, its incoming links can be viewed as votes supporting the page, and moreover the quality of the votes count through their importance as well as the number of votes that they make. Even if a minor page (with low PageRank) has many outgoing links, its contribution to the linked pages will not be substantial.

An interesting way to explain the PageRank is through the *random surfer model*: The random surfer starts from a randomly chosen page. Each time visiting a page, he/she follows a hyperlink in that page chosen at random with uniform probability. Hence, if the current page i has n_i outgoing links, then one of them is picked with probability $1/n_i$. If it happens that the current page has no outgoing link (e.g., at PDF documents), the surfer will use the back button. This process will be repeated. The PageRank value for a page

represents the probability of the surfer visiting the page. It is thus higher for pages visited more often by the surfer.

It is now clear that PageRank is obtained by describing the random surfer model as a Markov chain and then finding its stationary distribution. First, we express the network of web pages as the directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{1, 2, \dots, n\}$ is the set of nodes corresponding to web page indices, while $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ is the set of edges for links among pages. Node i is connected to node j by an edge, i.e., $(i, j) \in \mathcal{E}$, if page i has an outgoing link to page j .

Let $x_i(k)$ be the distribution of the random surfer visiting page i at time k , and let $x(k)$ be the vector containing all $x_i(k)$. Given the initial distribution $x(0)$, which is a probability vector, i.e., $\sum_{i=1}^n x_i(0) = 1$, the evolution of $x(k)$ can be expressed as

$$x(k+1) = Ax(k). \quad (1)$$

The link matrix $A = (a_{ij}) \in \mathbb{R}^{n \times n}$ is given by $a_{ij} = 1/n_j$ if $(j, i) \in \mathcal{E}$ and 0 otherwise, where n_j is the number of outgoing links of page j . Note that this matrix A is the transition probability matrix of the random surfer. Clearly, it is stochastic, and thus $x(k)$ remains a probability vector so that $\sum_{i=1}^n x_i(k) = 1$ for all k .

As mentioned above, PageRank is the stationary distribution of the process (1) under the assumption that the limit exists. Hence, the PageRank vector is given by $x^* := \lim_{k \rightarrow \infty} x(k)$. In other words, it is the solution of the linear equation

$$x^* = Ax^*, \quad x^* \in [0, 1]^n, \quad \mathbf{1}^T x^* = 1. \quad (2)$$

Notice that the PageRank vector x^* is a non-negative unit eigenvector for the eigenvalue 1 of A . Such a vector exists since the matrix A is stochastic but may not be unique; the reason is that A is a reducible matrix since in the web, not every pair of pages can be connected by simply following links. To resolve this issue, a slight modification is necessary in the random surfer model.

The idea of the *teleportation model* is that the random surfer, after a while, becomes bored and stops following the hyperlinks. At such an instant, the surfer “jumps” to another page not directly connected to the one currently visiting. This page can be in fact completely unrelated in the domains and/or the contents. All n pages in the web have the same probability $1/n$ to be reached by a jump.

The probability to make such a jump is denoted by $m \in (0, 1)$. The original transition probability matrix A is now replaced with the modified one $M \in \mathbb{R}^{n \times n}$ defined by

$$M := (1 - m)A + \frac{m}{n} \mathbf{1}\mathbf{1}^T. \quad (3)$$

For the value of m , we take $m = 0.15$ as reported in the original algorithm in Brin and Page (1998). Notice that M is a positive stochastic matrix. By Perron’s theorem (Horn and Johnson 1985), the eigenvalue 1 is of multiplicity 1 and is the unique eigenvalue with the maximum modulus. Further, the corresponding eigenvector is positive. Hence, we redefine the vector x^* in (2) by using M instead of A as follows:

$$x^* = Mx^*, \quad x^* \in [0, 1]^n, \quad \mathbf{1}^T x^* = 1. \quad (4)$$

Due to the large dimension of the link matrix M , the computation of x^* is difficult. The solution employed in practice is based on the power method given by

$$x(k+1) = Mx(k) = (1 - m)Ax(k) + \frac{m}{n} \mathbf{1}, \quad (5)$$

where the initial vector $x(0) \in \mathbb{R}^n$ is a probability vector. The second equality above follows from the fact $\mathbf{1}^T x(k) = 1$ for $k \in \mathbb{Z}_+$. For implementation, the form on the far right-hand side is important, using only the sparse matrix A and not the dense matrix M . This method asymptotically finds the value vector as $x(k) \rightarrow x^*, k \rightarrow \infty$.

Aggregation Methods for Large-Scale Markov Chains

In dealing with large-scale Markov chains, it is often desirable to predict their dynamic behaviors from reduced-order models that are more computationally tractable. This enables us, for example, to analyze the system performance at a macroscale with some approximation under different operating conditions. Aggregation refers to partitioning or grouping the states so that the states in each group can be treated as a whole. The technique of aggregation is especially effective for Markov chains possessing sparse structures with strong interactions among states in the same group and weak interactions among states in different groups. Such methods have been extensively studied, motivated by applications in queueing networks, power systems, etc. (Meyer 1989).

In the context of the PageRank problem, such sparse interconnection can be expressed in the link matrix A with a block-diagonal structure (after some coordinate change, if necessary). The entries of the matrix A are dense along its diagonal in blocks, and those outside the blocks take small values. More concretely, we write

$$A = I + B + \epsilon C, \quad (6)$$

where B is a block-diagonal matrix given as $B = \text{diag}(B_{11}, B_{22}, \dots, B_{NN})$; B_{ii} is the $\tilde{n}_i \times \tilde{n}_i$ matrix corresponding to the i th group with $\tilde{n}_i$ member pages for $i = 1, 2, \dots, N$; and ϵ is a small positive parameter. Here, the non-diagonal entries of B_{ii} are the same as those in the same diagonal block of A , but the diagonal entries are chosen such that $I + B_{ii}$ becomes stochastic and thus take nonpositive values. Thus, both B and C have column sums equal to zero. The small ϵ suggests us that states can be aggregated into N groups with strong interactions within the groups, but connections among different groups are weak. This class of Markov chains is known as nearly completely decomposable. In general, however, it is difficult to uniquely determine the form (6) for a given chain.

To exploit the sparse structure in the computation of stationary probability distributions, one approach is to carry out decomposition or aggregation of the chains. The basic approach here is (i) to compute the local stationary distributions for $I + B_{ii}$, (ii) to find the global stationary distribution for a chain representing the group interactions, and (iii) to finally use the obtained vectors to compute exact/approximate distribution for the entire chain; for details, see Meyer (1989). By interpreting such methods from the control theoretic viewpoints, in Phillips and Kokotovic (1981) and Aldaheri and Khalil (1991), singular perturbation approaches have been developed. These methods lead us to the two-time scale decomposition of (controlled) Markov chain recursions.

In the case of PageRank computation, sparsity is a relevant property since it is well-known that many links in the web are intra-host ones, connecting pages within the same domains or directories. However, in the real web, it is easy to find pages that have only a few outlinks, but some of them are external ones. Such pages will prevent the link matrix from having small ϵ when decomposed in the form (6). Hence, the general aggregation methods outlined above are not directly applicable.

An aggregation-based method suitable for PageRank computation is proposed in Ishii et al. (2012). There, the sparsity in the web is expressed by the limited number of external links pointing toward pages in other groups. For each page i , the node parameter $\delta_i \in [0, 1]$ is given by

$$\delta_i := \frac{\# \text{ external outgoing links}}{\# \text{ total outgoing links}}.$$

Note that smaller δ_i implies sparser networks. In this approach, for a given bound δ , the condition $\delta_i \leq \delta$ is imposed only in the case page i belongs to a group consisting of multiple members. Thus, a page forming a group by itself is not required to satisfy the condition. This means that we can regroup the pages by first identifying pages that violate this condition in the initial groups and then making them separately as *single* groups. By repeating these steps, it is always possible to

obtain groups for a given web. Once the grouping is settled, an aggregation-based algorithm can be applied, which computes an approximated PageRank vector. A characteristic feature is the trade-off between the accuracy in PageRank computation and the node parameter δ . More accurate computation requires a larger number of groups and thus a smaller δ .

Distributed Randomized Computation

For large-scale computation, distributed algorithms can be effective by employing multiple processors to compute in parallel. There are several methods of constructing algorithms to find stationary distributions of large Markov chains. In this section, motivated by the current literature on multi-agent systems, sequential distributed randomized approaches of gossip type are described for the PageRank problem.

In *gossip-type* distributed algorithms, nodes make decisions and transmit information to their neighbors in a random fashion. That is, at any time instant, each node decides whether to communicate or not depending on a random variable. The random property is important to make the communication asynchronous so that simultaneous transmissions resulting in collisions can be avoided. Moreover, there is no need of any centralized decision-maker or fixed order among pages.

More precisely, each page $i \in \mathcal{V}$ is equipped with a random process $\eta_i(k) \in \{0, 1\}$ for $k \in \mathbb{Z}_+$. If at time k , $\eta_i(k)$ is equal to 1, then page i broadcasts its information to its neighboring pages connected by outgoing links. All pages involved at this time renew their values based on the latest available data. Here, $\eta_i(k)$ is assumed to be an independent and identically distributed (i.i.d.) random process, and its probability distribution is given by $\text{Prob}\{\eta_i(k) = 1\} = \alpha$, $k \in \mathbb{Z}_+$. Hence, all pages are given the same probability α to initiate an update.

One of the proposed randomized approaches is based on the so-called asynchronous iteration algorithms for distributed computation of fixed

points in the field of numerical analysis (Bertsekas and Tsitsiklis 1989). The distributed update recursion is given as

$$\check{x}(k+1) = \check{M}_{\eta_1(k), \dots, \eta_n(k)} \check{x}(k), \quad (7)$$

where the initial state $\check{x}(0)$ is a probability vector, and the distributed link matrices $\check{M}_{p_1, \dots, p_n}$ are given as follows: Its (i, j) th entry is equal to $(1-m)a_{ij} + m/n$ if $p_i = 1$; 1 if $p_i = 0$ and $i = j$; and 0 otherwise. Clearly, these matrices keep the rows of the original link matrix M in (3) for pages initiating updates. Other pages just keep their previous values. Thus, these matrices are not stochastic. From this update recursion, the PageRank x^* is probabilistically obtained (in the mean square sense and in probability one), where the convergence speed is exponential in time k . Note that in this scheme (7), due to the way the distributed link matrices are constructed, each page needs to know which pages have links pointing toward it. This implies that popular pages linked by a number of pages must have extra memory to keep the data of such links.

Another recently developed approach Ishii and Tempo (2010) and Zhao et al. (2013) has several notable differences from the asynchronous iteration approach above. First, the pages need to transmit their states only over their outgoing links; the information of such links are by default available locally, and thus, pages are not required to have the extra memory regarding incoming links. Second, it employs stochastic matrices in the update as in the centralized scheme; this aspect is utilized in the convergence analysis. As a consequence, it is established that the PageRank vector x^* is computed in a probabilistic sense through the time average of the states $x(0), \dots, x(k)$ given by $y(k) := 1/(k+1) \sum_{\ell=0}^k x(\ell)$. The convergence speed in this case is of order $1/k$.

More recent studies have shown that exponential convergence is possible by distributed algorithms utilizing only outgoing links. The approaches in Lagoa et al. (2017) and You et al. (2017) are to view the PageRank problem as a least-square problem and thus employ distributed optimization techniques. On the other hand, in

Ishii and Suzuki (2018), an alternative approach is proposed by reinterpreting the PageRank problem and writing the PageRank vector x^* given in (4) in the form of a Neumann series as

$$x^* = \sum_{t=0}^{\infty} [(1-m)A]^t \frac{m}{n} \mathbf{1}.$$

A distributed algorithm based on this formulation is shown to have fast convergence speed there.

PageRank Optimization via Hyperlink Designs

For owners of websites, it is of particular interest to raise the PageRank values of their web pages. Especially in the area of e-business, this can be critical for increasing the number of visitors to their sites. The values of PageRank can be affected by changing the structure of hyperlinks in the owned pages. Based on the random surfer model, intuitively, it makes sense to arrange the links so that surfers will stay within the domain of the owners as long as possible.

PageRank optimization problems have rigorously been considered in, for example, de Kerchove et al. (2008), Fercoq et al. (2013), and Csáji et al. (2014). In general, these are combinatorial optimization problems since they deal with the issues on where to place hyperlinks, and thus the computation for solving them can be prohibitive especially when the web data is large. However, the work Fercoq et al. (2013) has shown that the problem can be solved in polynomial time. In what follows, we discuss a simplified discrete version of the problem setup of this work.

Consider a subset $\mathcal{V}_0 \subset \mathcal{V}$ of web pages over which a webmaster has control. The objective is to maximize the total PageRank of the pages in this set $\mathcal{V}_0$ by finding the outgoing links from these pages. Each page $i \in \mathcal{V}_0$ may have constraints such as links that must be placed within the page and those that cannot be allowed. All other links, i.e., those that one can decide to have or not, are the design parameters. Hence, the PageRank optimization problem can be stated as

$$\begin{aligned} \max \{ & U(x^*, M) : x^* = Mx^*, x^* \in [0, 1]^n, \\ & \mathbf{1}^T x^* = 1, M \in \mathcal{M} \}, \end{aligned}$$

where U is the utility function $U(x^*, M) := \sum_{i \in \mathcal{V}_0} x_i^*$ and $\mathcal{M}$ represents the set of admissible link matrices in accordance with the constraints introduced above.

In Fercoq et al. (2013), an extended continuous problem is also studied where the set $\mathcal{M}$ of link matrices is a polytope of stochastic matrices and a more general utility function is employed. The motivation for such a problem comes from having weighted links so that webmasters can determine which links should be placed in a more visible location inside their pages to increase clickings on those hyperlinks. Both discrete and continuous problems are shown to be solvable in polynomial time by modeling them as constrained Markov decision processes with ergodic rewards (see, e.g., Puterman 1994).

Summary and Future Directions

Markov chains form one of the simplest classes of stochastic processes but have been found powerful in their capability to model large-scale complex systems. In this entry, we introduced them mainly from the viewpoint of PageRank algorithms in the area of search engines and with a particular emphasis on recent works carried out based on control theoretic tools. Computational issues will remain in this area as major challenges, and further studies will be needed. As we have observed in PageRank-related problems, it is important to pay careful attention to structures of the particular problems.

Mathematical Models of Marine Vehicle-Manipulator Systems

Gianluca Antonelli

University of Cassino and Southern Lazio,
Cassino, Italy

Abstract

Marine intervention requires the use of manipulators mounted on support vehicles. Such systems, defined as vehicle-manipulator systems, exhibit specific mathematical properties and require proper control design methodologies. This article briefly discusses the mathematical model within a control perspective as well as sensing and actuation peculiarities.

Keywords

Marine robotics · Underwater robotics · Underwater intervention · Floating-base manipulators

Introduction

In case of marine operations that require interaction with the environment, an underwater vehicle is usually equipped with one or more manipulators; such systems are defined underwater vehicle-manipulator systems (UVMSs). A UVMS holding six degree-of-freedom (DOF) manipulators is illustrated in Fig. 1. The vehicle carrying the manipulator may or may not be connected to the surface; in the first case, we face a so-called remotely operated vehicle (ROV), while in the latter an autonomous underwater vehicle (AUV). ROVs, being physically linked,

via the tether, to an operator that can be on a submarine or on a surface ship, receives power as well as control commands. AUVs, on the other hand, are supposed to be completely autonomous, thus relying to onboard power system and intelligence.

Remotely controlled manipulation represents the state of the art in the underwater environment, while autonomous or semiautonomous operations still are in their embryonic stage. Activities in this direction are ongoing, such as, e.g., the European projects Trident (Sanz et al. 2013) and DexROV (Birk et al. 2018).

Sensory System

Any manipulation task requires that some variables are measured; those may concern the internal state of the system such as the end effector as well as the vehicle position and orientation or the velocities. Some others concern the surrounding environment as it is the case of vision systems or range measurements. The presence of the water, carrying the electromagnetic or acoustic signals, is such that the underwater sensing is characterized by poorer performance with respect to what the users are commonly used to in ground robotics.

One of the major challenges in underwater robotics is the localization due to the absence of a single, proprioceptive sensor that measures the vehicle position and the impossibility to use the Global Navigation Satellite System (GNSS) under the water. The use of redundant multi-sensory systems, thus, is common in order to perform sensor fusion and give fault detection and tolerance capabilities to the vehicle.

Localization

A possible approach for underwater vehicles localization is to rely on Inertial Navigation Systems (INSs); those are algorithms that implement dead reckoning techniques, i.e., the estimation of the position by properly merging and integrating measurements obtained with inertial and velocity sensors. Dead reckoning suffers from numerical drift due to the integration of sensor noise, as well as sensor bias and drift, and may be susceptible to the presence of external currents and model uncertainties. Since the variance of the estimation error grows with the distance traveled, this technique is only used for short dives.

Several algorithms are based on the concept of trilateration. The vehicle measures its distance with respect to known positions and prop-

erly uses this information by applying geometric-based formulas. Under the water, the technology for trilateration is not based on the electromagnetic field, due to the attenuation of its radiations, but on acoustics.

Among the commercially available solutions, long, short, and ultrashort baseline systems have found widespread use. The differences are in the baseline wavelength, the required distance among the transponders, the accuracy, and the installation cost. Acoustic underwater positioning is commercially mature, and several companies offer a variety of products.

In case of intervention, when the UVMS is close to the target, rather than the absolute position with respect to an inertial frame, it is crucial to estimate the relative position with respect to the target itself. In such a case, vision-based systems may be considered.

Actuation

Underwater vehicles are usually controlled by thrusters and/or control surfaces. Control surfaces, such as rudders and sterns, are typically used in vehicles working at cruise speed, i.e., torpedo-shaped vehicles usually used in monitoring or cable/pipeline inspection. In such vehicles a main thruster is used together with at least one rudder and one stern.

This configuration is unsuitable for UVMSs since the force/moment provided by the control surfaces is the function of the velocity, and it is null in hovering, when the manipulation is typically performed.

The relationship between the force/moment acting on the vehicle and the control input of the thrusters is highly nonlinear. It is the function of structural variables such as the density of the water, the tunnel cross-sectional area, the tunnel length, the volumetric flow rate between input and output of the thrusters, and the propeller diameter. The state of the dynamic system describing the thrusters is constituted by the propeller revolution, the speed of the fluid going into the propeller, and the input torque.

Modeling

UVMSs can be modeled as rigid bodies connected to form a serial chain; the vehicle is the floating base, while each link of the manipulator represents an additional rigid body with one DOF, typically the rotation around the corresponding joint's axis. Roughly speaking, modeling of a UVMS is the effort to represent the physical relationships of those bodies in order to measure and control its end effector, typically involved in a manipulation task.

The first step of modeling is the so-called direct kinematics, consisting in computing the position/orientation of the end effector with respect to an inertial, i.e., world fixed, frame. This is done via geometric relationship function of the system kinematic parameters, typically the lengths of the links, and the current system configuration, i.e., the vehicle position/orientation and the joint positions.

Velocities of each rigid body affect the following rigid bodies and thus the end effector. For example, a vehicle roll movement or the joint velocity is projected into a linear and angular end-effector velocity. This velocity transformation is studied by the differential kinematics. Analytic and/or geometric approaches may be used to retrieve those relationships. The study of the velocity-related equations is fundamental to understand how to balance the movement between vehicle and manipulator and, within the manipulator, how to distribute it among the joints. This topic is strictly related to differential, and inverse, kinematics for industrial robots.

The extension of Newton's second law to UVMSs leads to a number of nonlinear differential equations that link together the systems generalized forces and accelerations. With the word generalized forces, it is here intended as the forces and moments acting on the vehicle and the joint torques. Correspondingly, one is interested in the vehicle linear and angular accelerations and joint accelerations. Those equations couple together all the DOFs of the structure, e.g., a force applied to the vehicle causes acceleration also on the joints. Study of the dynamics is crucial to design the controller.

It is not possible to neglect that the bodies are moving in the water, the theory of fluidodynamics is rather complex, and it is difficult to develop a simple model for most of the hydrodynamic effects. A rigorous analysis for incompressible fluids would need to resort to the Navier-Stokes equations (distributed fluid flow). However, most of the hydrodynamic effects have no significant influence in the range of the operative velocities for UVMS intervention tasks with the exception of the added masses, the linear and quadratic damping terms, and the buoyancy.

Control

Not surprisingly, the mathematical model of UVMS shares most of the characteristics of industrial robots as well as space robots modeling. Having taken into account to the physical differences, the control problems are also similar:

- **Kinematic control.** The control problem is given in terms of motion of the end effector and needs to be transformed into the motion of the vehicle and the manipulator. This is often approached by resorting to the inverse differential kinematic algorithms. In particular, algorithms for redundant systems need to be considered since a UVMS always possess at least six DOFs. Moving a UVMS requires to handle additional variables with respect to the end effector such as the vehicle roll and pitch to preserve energy, the robot manipulability, the mechanical joint limits, or eventual directional sensing.
- **Motion control.** Low-level control algorithms are designed to allow the system tracking the desired trajectory. UVMSs are characterized by different dynamics between vehicle and manipulator, uncertainty in the model parameter knowledge, poor sensing performance, and limit cycle in the thruster model. On the other hand, the limited bandwidth of the closed-loop system allows the use of simple control approaches.
- **Interaction control.** Several applications require exchange of forces with the environment. A pure motion control algorithm is not devised for such operation and specific force control algorithms, both direct and indirect, may be necessary. Master/slave systems or haptic devices may be used on the purpose, while autonomous interaction control still is in the research phase for the marine environment.

Summary and Future Directions

This article is aimed at giving a short overview of the main mathematical and technological challenges arising with UVMSs. All the components of an underwater mission, perception, actuation, and communication with the surface, are characterized by poorer performances with respect to the current industrial or advanced robotics applications.

The underwater environment is hostile; as an example the marine current provides disturbances to be counteracted by the dynamic controller, or the sand's whirlwinds obfuscate the vision-based operations close to the sea bottom. Both tele-operated and autonomous underwater missions require a significant human effort in planning, testing, and monitoring all the operations. Fault detection and recovery policies are necessary in each step to avoid loss of expensive hardware.

Future generation of UVMSs needs to be autonomous, to percept and contextualize the environment, to react with respect to unplanned situations, and to safely reschedule the tasks of complex missions. Those characteristics are being shared by all the branches of the service robotics.

Recommended Reading

The book of T. Fossen (1994) is one of the first books dedicated to control problems of marine systems, both underwater and surface. The same author presents, in Fossen (2002), an updated and extended version of the topics developed in the first book and in Fossen (2011), a handbook on marine craft hydrodynamics and control. A short introductory chapter to marine robotics may be found in Antonelli et al. (2016). Robotics fundamentals are also useful and can be found in Siciliano et al. (2009). At the best of our knowledge, Antonelli (2018) is the only monograph devoted to addressing the specific problems of underwater vehicle-manipulator systems.

Mathematical Models of Ships and Underwater Vehicles

Thor I. Fossen

Department of Engineering Cybernetics, Centre for Autonomous Marine Operations and Systems, Norwegian University of Science and Technology, Trondheim, Norway

Abstract

This entry describes the equations of motion of ships and underwater vehicles. Standard hydrodynamic models in the literature are reviewed and presented using the nonlinear robot-like vectorial notation of Fossen (1991, 1994, 2011). The matrix-vector notation is highly advantageous when designing control systems since well-known system properties such as symmetry, skew-symmetry, and positiveness can be exploited in the design.

Keywords

Autonomous underwater vehicle (AUV) · Degrees of freedom · Euler angles · Hydrodynamics · Kinematics · Kinetics · Maneuvering · Remotely operated vehicle (ROV) · Seakeeping · Ship · Underwater vehicles

Introduction

The subject of this entry is mathematical modeling of ships and underwater vehicles. With *ship* we mean “any large floating vessel capable of crossing open waters,” as opposed to a boat, which is generally a smaller craft. An *underwater vehicle* is a “small vehicle that is capable of propelling itself beneath the water surface as well as on the water’s surface.” This includes unmanned underwater vehicles (UUVs), remotely operated vehicles (ROVs), autonomous underwater vehicles (AUVs) and underwater robotic vehicles (URVs).

This entry is based on Fossen (1991, 2011), which contains a large number of standard models for ships, rigs, and underwater vehicles. There exist a large number of textbooks on mathematical modeling of ships; see Rawson and Tupper (1994), Lewandowski (2004), and Perez (2005). For underwater vehicles, see Allmendinger (1990), Sutton and Roberts (2006), Inzartsev (2009), Anotonelli (2010), and Wadoo and Kachroo (2010). Some useful references on ship hydrodynamics are Newman (1977), Faltinsen (1990), and Bertram (2012).

Degrees of Freedom

A mathematical model of marine craft is usually represented by a set of ordinary differential equations (ODEs) describing the motions in six degrees of freedom (DOF): *surge*, *sway*, *heave*, *roll*, *pitch*, and *yaw*.

Hydrodynamics

In hydrodynamics it is common to distinguish between two theories:

- **Seakeeping theory:** The motions of ships at zero or constant speed in waves are analyzed using hydrodynamic coefficients and wave forces, which depends of the wave excitation frequency and thus the hull geometry and mass distribution. For underwater vehicles operating below the wave-affected zone, the wave excitation frequency will not influence the hydrodynamic coefficients.
- **Maneuvering theory:** The ship is moving in restricted calm water – that is, in sheltered waters or in a harbor. Hence, the maneuvering model is derived for a ship moving at positive speed under a zero-frequency wave excitation assumption such that added mass and damping can be represented by constant parameters.

Seakeeping models are typically used for ocean structures and dynamically positioned vessels. Several hundred ODEs are needed to effectively represent a seakeeping model; see Fossen (2011), and Perez and Fossen (2011a, b).

The remainder of this entry assumes *maneuvering theory*, since this gives lower-order models typically suited for controller-observer design. Six ODEs are needed to describe the *kinematics*, that is, the geometrical aspects of motion while Newton-Euler's equations represent additional six ODEs describing the forces and moments causing the motion (*kinetics*).

Notation

The equations of motion are usually represented using generalized position, velocity and forces (Fossen 1991, 1994, 2011) defined by the state vectors:

$$\boldsymbol{\eta} := [x, y, z, \phi, \theta, \psi]^T \quad (1)$$

$$\boldsymbol{v} := [u, v, w, p, q, r]^T \quad (2)$$

$$\boldsymbol{\tau} := [X, Y, Z, K, M, N]^T \quad (3)$$

where $\boldsymbol{\eta}$ is the generalized position expressed in the north-east-down (NED) reference frame $\{n\}$. A body-fixed reference frame $\{b\}$ with axes:

x_b – longitudinal axis (from aft to fore)

y_b – transversal axis (to starboard)

z_b – normal axis (directed downward)

is rotating about the NED reference frame $\{n\}$ with angular velocity $\boldsymbol{\omega} = [p, q, r]^T$. The generalized velocity vector $\boldsymbol{v}$ and forces $\boldsymbol{\tau}$ are both expressed in $\{b\}$, and the 6-DOF states are defined according to SNAME (1950):

- **Surge** position x , linear velocity u , force X
- **Sway** position y , linear velocity v , force Y
- **Heave** position z , linear velocity w , force Z
- **Roll** angle ϕ , angular velocity p , moment K
- **Pitch** angle θ , angular velocity q , moment M
- **Yaw** angle ψ , angular velocity r , moment N

Kinematics

The generalized velocities $\dot{\boldsymbol{\eta}}$ and $\boldsymbol{v}$ in $\{b\}$ and $\{n\}$, respectively satisfy the following kinematic transformation (Fossen 1994, 2011):

$$\dot{\eta} = \mathbf{J}(\eta) \mathbf{v} \quad (4)$$

$$\mathbf{J}(\eta) := \begin{bmatrix} \mathbf{R}(\Theta) & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{T}(\Theta) \end{bmatrix} \quad (5)$$

where $\Theta = [\phi, \theta, \psi]^\top$ is the *Euler angles* and

$$\mathbf{R}(\Theta) = \begin{bmatrix} c\psi c\theta & -s\psi c\theta + c\psi s\theta s\phi & s\psi c\theta + c\psi s\theta c\phi \\ s\psi c\theta & c\psi c\theta + s\psi s\theta s\phi & c\psi c\theta + s\psi s\theta c\phi \\ -s\theta & c\theta s\phi & c\theta c\phi \end{bmatrix} \quad (6)$$

with $s \cdot = \sin(\cdot)$, $c \cdot = \cos(\cdot)$ and $t \cdot = \tan(\cdot)$.

The matrix $\mathbf{R}$ is recognized as the Euler angle rotation matrix $\mathbf{R} \in SO(3)$ satisfying $\mathbf{R}\mathbf{R}^\top = \mathbf{R}^\top\mathbf{R} = \mathbf{I}$, and $\det(\mathbf{R}) = 1$, which implies that $\mathbf{R}$ is orthogonal. Consequently, the inverse rotation matrix is given by: $\mathbf{R}^{-1} = \mathbf{R}^\top$. The Euler rates $\dot{\Theta} = \mathbf{T}(\Theta)\omega$ are singular for $\theta \neq \pm\pi/2$ since:

$$\mathbf{T}(\Theta) = \begin{bmatrix} 1 & s\phi t\theta & c\phi t\theta \\ 0 & c\phi & -s\phi \\ 0 & s\phi/c\theta & c\phi/c\theta \end{bmatrix}, \quad \theta \neq \pm\frac{\pi}{2} \quad (7)$$

Singularities can be avoided by using *unit quaternions* instead (Fossen 1994, 2011).

Kinetics

The rigid-body kinetics can be derived using the *Newton-Euler formulation*, which is based on *Newton's second law*. Following Fossen (1994, 2011) this gives:

$$\mathbf{M}_{RB}\dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v} = \boldsymbol{\tau}_{RB} \quad (8)$$

where $\mathbf{M}_{RB}$ is the rigid-body mass matrix, $\mathbf{C}_{RB}$ is the rigid-body Coriolis and centripetal matrix due to the rotation of $\{b\}$ about the geographical frame $\{n\}$. The generalized force vector $\boldsymbol{\tau}_{RB}$ represents external forces and moments expressed in $\{b\}$. In the nonlinear case:

$$\boldsymbol{\tau}_{RB} = -\mathbf{M}_A\dot{\mathbf{v}} - \mathbf{C}_A(\mathbf{v})\mathbf{v} - \mathbf{D}(\mathbf{v})\mathbf{v} - \mathbf{g}(\eta) + \boldsymbol{\tau} \quad (9)$$

where the matrices $\mathbf{M}_A$ and $\mathbf{C}_A(\mathbf{v})$ represent hydrodynamic added mass due to acceleration $\dot{\mathbf{v}}$ and Coriolis acceleration due to the rotation of $\{b\}$ about the geographical frame $\{n\}$. The potential and viscous damping terms are lumped together into a nonlinear matrix $\mathbf{D}(\mathbf{v})$ while $\mathbf{g}(\eta)$ is a vector of generalized restoring forces. The control inputs are generalized forces given by $\boldsymbol{\tau}$.

Formulae (8) and (9) together with (4) are the fundamental equations when deriving the ship and underwater vehicle models. This is the topic for the next sections.

Ship Model

The ship equations of motion are usually represented in three DOFs by neglecting *heave*, *roll* and *pitch*. Combining (4), (8), and (9) we get:

$$\dot{\eta} = \mathbf{R}(\psi)\mathbf{v} \quad (10)$$

$$\mathbf{M}\dot{\mathbf{v}} + \mathbf{C}(\mathbf{v})\mathbf{v} + \mathbf{D}(\mathbf{v})\mathbf{v} = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{wave}} \quad (11)$$

where $\eta := [x, y, \psi]^\top$, $\mathbf{v} := [u, v, r]^\top$ and

$$\mathbf{R}(\psi) = \begin{bmatrix} c\psi & -s\psi & 0 \\ s\psi & c\psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (12)$$

is the rotation matrix in yaw. It is assumed that wind and wave-induced forces $\boldsymbol{\tau}_{\text{wind}}$ and $\boldsymbol{\tau}_{\text{wave}}$ can be linearly superpositioned. The system matrices $\mathbf{M} = \mathbf{M}_{RB} + \mathbf{M}_A$ and $\mathbf{C}(\mathbf{v}) = \mathbf{C}_{RB}(\mathbf{v}) + \mathbf{C}_A(\mathbf{v})$ are usually derived under the assumption of port-starboard symmetry and that surge can be decoupled from sway and yaw (Fossen 2011). Moreover,

$$\mathbf{M} = \begin{bmatrix} m - X_{\dot{u}} & 0 & 0 \\ 0 & m - Y_{\dot{v}} & mx_g - Y_{\dot{r}} \\ 0 & mx_g - N_{\dot{v}} & I_z - N_{\dot{r}} \end{bmatrix} \quad (13)$$

$$\mathbf{C}_{RB}(\mathbf{v}) = \begin{bmatrix} 0 & -mr & -mx_g r \\ mr & 0 & 0 \\ mx_g r & 0 & 0 \end{bmatrix} \quad (14)$$

$$\mathbf{C}_A(\mathbf{v}) = \begin{bmatrix} 0 & 0 & Y_{\dot{v}}v + Y_{\dot{r}}r \\ 0 & 0 & -X_{\dot{u}}u \\ -Y_{\dot{v}}v - Y_{\dot{r}}r & X_{\dot{u}}u & 0 \end{bmatrix} \quad (15)$$

Hydrodynamic damping will, in its simplest form, be linear:

$$\mathbf{D} = \begin{bmatrix} -X_u & 0 & 0 \\ 0 & -Y_v & -Y_r \\ 0 & -N_r & -N_r \end{bmatrix} \quad (16)$$

while a nonlinear expression based on second-order modulus functions describing quadratic drag and cross-flow drag is:

$$\mathbf{D}(\mathbf{v}) = \begin{bmatrix} -X_{|u|u} |u| & 0 \\ 0 & -Y_{|v|v} |v| - Y_{|r|v} |r| \\ 0 & -N_{|v|v} |v| - N_{|r|v} |r| \\ 0 & -Y_{|v|r} |v| - Y_{|r|r} |r| \\ -N_{|v|r} |v| - N_{|r|r} |r| \end{bmatrix} \quad (17)$$

Other nonlinear representations are found in Fossen (1994, 2011).

In the case of *irrotational ocean currents*, we introduce the relative velocity vector:

$$\mathbf{v}_r = \mathbf{v} - \mathbf{v}_c$$

where $\mathbf{v}_c = [u_c^b, v_c^b, 0]^\top$ is a vector of current velocities in $\{b\}$. Hence, the kinetic model takes the form:

$$\begin{aligned} & \underbrace{\mathbf{M}_{RB} \dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v}) \mathbf{v}}_{\text{rigid-body forces}} \\ & + \underbrace{\mathbf{M}_A \dot{\mathbf{v}}_r + \mathbf{C}_A(\mathbf{v}_r) \mathbf{v}_r + \mathbf{D}(\mathbf{v}_r) \mathbf{v}_r}_{\text{hydrodynamic forces}} \\ & = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{wave}} \end{aligned}$$

This model can be simplified if the *ocean currents* are assumed to be *constant* and *irrotational* in $\{n\}$. According to Fossen (1994, 2011, Property 8.1), $\mathbf{M}_{RB} \dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v}) \mathbf{v} \equiv \mathbf{M}_{RB} \dot{\mathbf{v}}_r + \mathbf{C}_{RB}(\mathbf{v}_r) \mathbf{v}_r$ if the rigid-body Coriolis and centripetal matrix satisfies $\mathbf{C}_{RB}(\mathbf{v}_r) = \mathbf{C}_{RB}(\mathbf{v})$. One parametrization satisfying this is (14). Hence, the Coriolis and centripetal matrix satisfies $\mathbf{C}(\mathbf{v}_r) = \mathbf{C}_{RB}(\mathbf{v}_r) + \mathbf{C}_A(\mathbf{v}_r)$ and it follows that:

$$\mathbf{M} \dot{\mathbf{v}}_r + \mathbf{C}(\mathbf{v}_r) \mathbf{v}_r + \mathbf{D}(\mathbf{v}_r) \mathbf{v}_r = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{wave}} \quad (18)$$

The kinematic equation (10) can be modified to include the relative velocity $\mathbf{v}_r$ according to:

$$\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi) \mathbf{v}_r + [u_c^n, v_c^n, 0]^\top \quad (19)$$

where the ocean current velocities $u_c^n = \text{constant}$ and $v_c^n = \text{constant}$ in $\{n\}$. Notice that the body-fixed velocities $\mathbf{v}_c = \mathbf{R}(\psi)^\top [u_c^n, v_c^n, 0]^\top$ will vary with the heading angle ψ .

The maneuvering model presented in this entry is intended for controller-observer design, prediction, and computer simulations, as well as system identification and parameter estimation. A large number of application-specific models for marine craft are found in Fossen (1994, 2011, Chap. 7).

Hydrodynamic programs compute mass, inertia, potential damping and restoring forces while a more detailed treatment of viscous dissipative forces (damping) and sealoads are found in the extensive literature on hydrodynamics – see Faltinsen (1990) and Newman (1977).

Underwater Vehicle Model

The 6-DOF underwater vehicle equations of motion follow from (4), (8), and (9) under the assumption that wave-induced motions can be neglected:

$$\dot{\boldsymbol{\eta}} = \mathbf{J}(\boldsymbol{\eta}) \mathbf{v} \quad (20)$$

$$\mathbf{M} \dot{\mathbf{v}} + \mathbf{C}(\mathbf{v}) \mathbf{v} + \mathbf{D}(\mathbf{v}) \mathbf{v} + \mathbf{g}(\boldsymbol{\eta}) = \boldsymbol{\tau} \quad (21)$$

with generalized position $\boldsymbol{\eta} := [x, y, z, \phi, \theta, \psi]^\top$ and velocity $\mathbf{v} := [u, v, w, p, q, r]^\top$. Assume

that the gravitational force acts through the center of gravity (CG) defined by the vector $\mathbf{r}_g := [x_g, y_g, z_g]^\top$ with respect to the coordinate origin $\{b\}$. Similarly, the buoyancy force acts through the center of buoyancy (CB) defined by

the vector $\mathbf{r}_b := [x_b, y_b, z_b]^\top$. For most vehicles $y_g = y_b = 0$.

For a port-starboard symmetrical vehicle with homogenous mass distribution, CG satisfying $y_g = 0$ and products of inertia $I_{xy} = I_{yz} = 0$, the system inertia matrix becomes:

$$\mathbf{M} := \begin{bmatrix} m - X_{\dot{u}} & 0 & -X_{\dot{w}} & 0 & mz_g - X_{\dot{q}} & 0 \\ 0 & m - Y_{\dot{v}} & 0 & -mz_g - Y_{\dot{p}} & 0 & mx_g - Y_{\dot{r}} \\ -X_{\dot{w}} & 0 & m - Z_{\dot{w}} & 0 & -mx_g - Z_{\dot{q}} & 0 \\ 0 & -mz_g - Y_{\dot{p}} & 0 & I_x - K_{\dot{p}} & 0 & -I_{zx} - K_{\dot{r}} \\ mz_g - X_{\dot{q}} & 0 & -mx_g - Z_{\dot{q}} & 0 & I_y - M_{\dot{q}} & 0 \\ 0 & mx_g - Y_{\dot{r}} & 0 & -I_{zx} - K_{\dot{r}} & 0 & I_z - N_{\dot{r}} \end{bmatrix} \quad (22)$$

where the hydrodynamic derivatives are defined according to SNAME (1950). The Coriolis and centripetal matrices are:

$$\mathbf{C}_A(\mathbf{v}) = \begin{bmatrix} 0 & 0 & 0 & 0 & -a_3 & a_2 \\ 0 & 0 & 0 & a_3 & 0 & -a_1 \\ 0 & 0 & 0 & -a_2 & a_1 & 0 \\ 0 & -a_3 & a_2 & 0 & -b_3 & b_2 \\ a_3 & 0 & -a_1 & b_3 & 0 & -b_1 \\ -a_2 & a_1 & 0 & -b_2 & b_1 & 0 \end{bmatrix} \quad (23)$$

where

$$\begin{aligned} a_1 &= X_{\dot{u}}u + X_{\dot{w}}w + X_{\dot{q}}q \\ a_2 &= Y_{\dot{v}}v + Y_{\dot{p}}p + Y_{\dot{r}}r \\ a_3 &= Z_{\dot{u}}u + Z_{\dot{w}}w + Z_{\dot{q}}q \\ b_1 &= K_{\dot{v}}v + K_{\dot{p}}p + K_{\dot{r}}r \\ b_2 &= M_{\dot{u}}u + M_{\dot{w}}w + M_{\dot{q}}q \\ b_3 &= N_{\dot{v}}v + N_{\dot{p}}p + N_{\dot{r}}r \end{aligned} \quad (24)$$

and

$$\mathbf{C}_{RB}(\mathbf{v}) = \begin{bmatrix} 0 & -mr & mq & mz_g r & -mx_g q & -mx_g r \\ mr & 0 & -mp & 0 & m(z_g r + x_g p) & 0 \\ -mq & mp & 0 & -mz_g p & -mz_g q & mx_g p \\ -mz_g r & 0 & mz_g p & 0 & -I_{xz} p + I_z r & -I_y q \\ mx_g q & -m(z_g r + x_g p) & mz_g q & I_{xz} p - I_z r & 0 & -I_{xz} r + I_x p \\ mx_g r & 0 & -mx_g p & I_y q & I_{xz} r - I_x p & 0 \end{bmatrix} \quad (25)$$

Notice that this representation of $\mathbf{C}_{RB}(\mathbf{v})$ only depends on the angular velocities p , q , and r , and not the linear velocities u , v , and r . This

property will be exploited when including drift due to ocean currents.

Linear damping for a port-starboard symmetrical vehicle takes the following form:

$$\mathbf{D} = - \begin{bmatrix} X_u & 0 & X_w & 0 & X_q & 0 \\ 0 & Y_v & 0 & Y_p & 0 & Y_r \\ Z_u & 0 & Z_w & 0 & Z_q & 0 \\ 0 & K_v & 0 & K_p & 0 & K_r \\ M_u & 0 & M_w & 0 & M_q & 0 \\ 0 & N_v & 0 & N_p & 0 & N_r \end{bmatrix} \quad (26)$$

Let $W = mg$ and $B = \rho g \nabla$ denote the weight and buoyance where m is the mass of the vehicle including water in free floating space, ∇ the volume of fluid displaced by the vehicle, g the acceleration of gravity (positive downward), and ρ the water density. Hence, the generalized restoring forces for a vehicle satisfying $y_g = y_b = 0$ becomes (Fossen 1994, 2011):

$$\mathbf{g}(\boldsymbol{\eta}) = \begin{bmatrix} (W - B)s\theta \\ -(W - B)c\theta s\phi \\ -(W - B)c\theta c\phi \\ (z_g W - z_b B)c\theta s\phi \\ (z_g W - z_b B)s\theta + (x_g W - x_b B)c\theta c\phi \\ -(x_g W - x_b B)c\theta s\phi \end{bmatrix} \quad (27)$$

The expression for $\mathbf{D}$ can be extended to include nonlinear damping terms if necessary. Quadratic damping is important at higher speeds since the Coriolis and centripetal terms $\mathbf{C}(\mathbf{v})\mathbf{v}$ can destabilize the system if only linear damping is used.

In the presence of irrotational ocean currents, we can rewrite (20) and (21) in terms of relative velocity $\mathbf{v}_r = \mathbf{v} - \mathbf{v}_c$ according to:

$$\dot{\boldsymbol{\eta}} = \mathbf{J}(\boldsymbol{\eta})\mathbf{v}_r + [u_c^n, v_c^n, w_c^n, 0, 0, 0]^T \quad (28)$$

$$\mathbf{M}\dot{\mathbf{v}}_r + \mathbf{C}(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}(\mathbf{v}_r)\mathbf{v}_r + \mathbf{g}(\boldsymbol{\eta}) = \boldsymbol{\tau} \quad (29)$$

where it is assumed that $\mathbf{C}_{RB}(\mathbf{v}_r) = \mathbf{C}_{RB}(\mathbf{v})$, which clearly is satisfied for (25). In addition, it is assumed that u_c^n , v_c^n , and w_c^n are constant. For more details see Fossen (2011).

Programs and Data

The Marine Systems Simulator (MSS) is a Matlab/Simulink library and simulator for marine craft (<http://www.marinecontrol.org>). It includes

models for ships, underwater vehicles, and floating structures.

Summary and Future Directions

This entry has presented standard models for simulation of ships and underwater vehicles. It is recommended to consult Fossen (1994, 2011) for a more detailed description of marine craft hydrodynamics.

Matrix Equations in Control

Vasile Sima

National Institute for Research and Development in Informatics, Bucharest, Romania

Abstract

Linear and quadratic (Riccati) matrix equations are fundamental for systems and control theory and its numerous applications. Generalized or standard Sylvester and Lyapunov equations and generalized Riccati equations for continuous- and discrete-time systems are considered. Essential applications in control are mentioned. The main solvability conditions and properties of these equations, as well as state-of-the-art solution techniques, are summarized. The continuous progress in this area paves the way for further developments and extensions to more complex control problems.

algorithm · Observability · Performance index · Riccati equation · Schur decomposition · Stability · Stein equation · Sylvester equation

Introduction

Matrix equations are algebraic equations in which the given data and the unknown values are represented by matrices. They appear in many computational techniques in control and systems theory and its applications but also in numerous other engineering and scientific domains. The general definition above includes linear systems of equations, $AX = B$, where $A \in \mathbb{C}^{m \times n}$ and $B \in \mathbb{C}^{m \times p}$ are given complex matrices and $X \in \mathbb{C}^{n \times p}$ is the unknown matrix. Depending on A and B , such a system may have one solution, infinitely many solutions, or no solution. If $m = n$ and A is nonsingular, then $X = A^{-1}B$ is the unique solution, where A^{-1} denotes the inverse of A . If $m \geq n$, but some columns of B are not in the range space of A , there is no (exact) solution X . However, least-squares solutions minimizing $\|AX_i - B_i\|_2^2$, for each $i = 1, 2, \dots, p$, can be computed. Here, $\|\cdot\|_2$ denotes the Euclidean norm of a vector, and M_i is the i -th column of the matrix M . If $\text{rank}(A) = n$, the least-squares solution is unique. If $\text{rank}(A) < n$, the solution is not unique, and a least-squares solution of minimum norm can be defined using the Moore-Penrose generalized inverse of A . For numerical reasons, (generalized) inverses are not used in practice, but suitable decompositions of A are computed, and each X_i is obtained by solving a linear system, possibly in a least-squares sense (Golub and Van Loan 2013). These simple matrix equations will no longer be discussed in this entry, but equations in which the unknown matrix X appears several times will be considered. The most used matrix equations in control are linear matrix equations and quadratic matrix equations in X . Since most control applications use real matrices, the real case only will be dealt with in the remaining sections. Extensions to the complex case are relatively straightforward.

Matrix Equations in Control Theory and Its Applications

Linear Matrix Equations

A general form of the linear matrix equations encountered in control theory and its applications is expressed by the *generalized Sylvester equation*,

$$AXD + EXF = -H, \quad (1)$$

where A , D , E , F , and H are known matrices with compatible dimensions and X is an unknown matrix. If D and E are identity matrices (denoted I , the order being implied), then (1) is the *Sylvester equation*, named after J. J. Sylvester, who defined it in 1884. If, in addition, $F = A^T$ and H is symmetric, that is, $H = H^T$, where the superscript denotes matrix transposition, then (1) is the (*continuous-time*) *Lyapunov equation*, named after A. M. Lyapunov, who published in 1892 an inspiring paper on the stability of motion. If $D = A^T$, $E = I$, $F = -I$, and $H = H^T$, then (1) is a *discrete-time Lyapunov equation*, sometimes called *Stein equation*. By analogy, (1) with $E = I$, $F = I$, and general H may be called *discrete-time Sylvester equation*. Moreover, if $F = A^T$, $D = E^T \neq I$, and $H = H^T$, then (1) is a *generalized continuous-time Lyapunov equation*, and if $D = A^T$, $F = -E^T \neq I$, and $H = H^T$, then (1) is a *generalized discrete-time Lyapunov equation*. For convenience, the generalized Lyapunov equations are explicitly written,

$$AXE^T + EXA^T = -H, \quad (2)$$

$$AXA^T - EXE^T = -H. \quad (3)$$

Standard Lyapunov equations are obtained from (2) and (3) for $E = I$. The symmetry of Lyapunov equations and of H implies that the solution, if it exists, is also symmetric, $X = X^T$.

Equation (1) has a unique solution if and only if the matrix pencils $A - \lambda D$ and $F - \lambda E$ are regular, that is, $\det(A - \lambda E) \neq 0$, $\det(F - \lambda D) \neq 0$, for $\lambda \in \mathbb{C}$, and $\Lambda(A - \lambda E) \cap \Lambda(F + \lambda D) = \emptyset$, that is, the spectra of the pencils $A - \lambda E$ and $F + \lambda D$ are disjoint. Here, $\Lambda(M - \lambda N)$ denotes the set of eigenvalues of the matrix pencil $M - \lambda N$,

and $\emptyset$ is the empty set. Without loss of generality, it can be assumed that matrix E in (2) and (3) is nonsingular. Then, (2) has a solution if $\lambda_i + \lambda_j \neq 0$, for all $\lambda_i, \lambda_j \in \Lambda(A - \lambda E)$. Similarly, (3) has a solution if $\lambda_i \lambda_j \neq 1$. Solvability conditions for standard Lyapunov equations follow simply by setting $E = I$, and so, they are related to the spectrum of A , $\Lambda(A) := \Lambda(A - \lambda I)$.

Sylvester systems (i.e., two coupled linear matrix equations) are employed, for instance, to simultaneously block-diagonalize two square matrices. Solving Sylvester equations is also needed for block-diagonalization of a matrix or for designing Luenberger observers. Lyapunov equations are key mathematical objects in systems theory, in analysis and design of control systems, and in many applications. Solving Lyapunov equations is an essential step in balanced realization algorithms, in procedures for computing reduced order models for systems or controllers, in Newton methods for algebraic Riccati equations (AREs), or in stabilization algorithms; see, for example, Benner et al. (2005), Lancaster and Rodman (1995), Mehrmann (1991), and Sima (1996) and the references therein. Stability analyses for dynamical systems may also resort to Lyapunov equations. A comprehensive recent survey of the theory and applications of linear matrix equations in various domains is Simoncini (2016).

The standard continuous- and discrete-time Lyapunov equations,

$$AX + XA^T = -H, \quad (4)$$

$$AXA^T - X = -H, \quad (5)$$

with $H = H^T$, are associated with an autonomous linear time-invariant system, described by

$$\delta(x(t)) = Ax(t), \quad t \geq 0, \quad x(0) = x_0, \quad (6)$$

where $x(t) \in \mathbb{R}^n$ is the system state and $\delta(x(t))$ is either $dx(t)/dt$, the differential operator, or $x(t+1)$, the advance difference operator, respectively. A necessary and sufficient condition for asymptotic stability of the system (6) is that for any symmetric positive definite matrix H ,

denoted $H > 0$, there is a unique solution $X > 0$ of the Lyapunov equation (4) or (5). Moreover, if H is positive semi-definite, denoted $H \geq 0$, and $X > 0$, then all trajectories of $x(t)$ in (6) are bounded. If, in addition, the pair (A, H) is controllable, that is, $\text{rank}([A - \lambda I \ H]) = n$, for all $\lambda \in \Lambda(A)$, then the system (6) is globally asymptotically stable. Another sufficient condition for global asymptotic stability is that $H > 0$ and $X > 0$. If $H \geq 0$ and $X \not\geq 0$, then A is not stable. If $z(t)$ is a trajectory of (6), and $V(z) := z^T X z$, then $\frac{dV(z)}{dt} = -z^T H z$, in the continuous-time case, and $V(z(t+1)) - V(z(t)) = -z^T H z$, in the discrete-time case. The function $V(z)$ is a quadratic *Lyapunov function*. If $X > 0$, then $V(z) = 0$ implies $z = 0$.

A necessary solvability condition is that both A and E , for (2), or either A or E , for (3), is nonsingular. If $\Lambda(A, E) \subset \mathbb{C}_-$, where $\mathbb{C}_-$ is the open left half of the complex plane $\mathbb{C}$, in the continuous-time case, or the open unit disk centered in the origin of $\mathbb{C}$, in the discrete-time case, then (2) or (3) are *stable* Lyapunov equations. If $H \geq 0$, a stable Lyapunov equation has a unique solution $X \geq 0$ that can be expressed and computed in a factored form, $X = U^T U$, where U is a (lower or upper triangular) Cholesky factor of X (Hammarling 1982).

An important application is the computation of the Hankel singular values of a dynamical system,

$$\begin{aligned} E\dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t), \quad x(0) = x_0, \end{aligned} \quad (7)$$

where $A, E \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, and $C \in \mathbb{R}^{p \times n}$ and $u(t)$ and $y(t)$ are the inputs (controls) and measured outputs at time t . Two related Lyapunov equations are defined for this system,

$$\begin{aligned} APE^T + EPA^T &= -BB^T, \\ A^T QE + E^T QA &= -C^T C, \end{aligned} \quad (8)$$

in the continuous-time case, and

$$\begin{aligned} APA^T - EPE^T &= -BB^T, \\ A^T QA - E^T QE &= -C^T C, \end{aligned} \quad (9)$$

in the discrete-time case. The solutions P and Q of these equations are the *controllability* and *observability Gramians*, respectively, of (7). The *Hankel singular values* are the nonnegative square roots of the eigenvalues of the matrix product QP . If the system (7) is stable, then $P \geq 0$ and $Q \geq 0$, and these properties imply that $QP \geq 0$. But these theoretical results may not hold in numerical computations if the symmetry and semi-definiteness are not preserved by a solver. The recommended approach for this application, proposed in Penzl (1998), uses B and C directly, without evaluating BB^T and $C^T C$, and computes the upper triangular Choleky factors R_c and R_o of the Gramians, $P = R_c R_c^T$, $Q = R_o^T R_o$. The Hankel singular values are then obtained as the singular values of the product $R_o R_c$, which are all real nonnegative. The Gramians and the Hankel singular values are used, for instance, for finding balanced realizations and reduced order models.

Many techniques have been proposed for solving linear matrix equations. Some techniques use integrals of products of matrix exponentials or of the resolvents $(A - \lambda E)^{-1}$ and $(F - \lambda D)^{-1}$. For instance, the unique solution of a Sylvester equation is $X = \int_0^\infty e^{At} H e^{Ft} dt$, if this integral exists. However, the most used techniques for small- and medium-size equations (with orders less than a few thousands) are techniques based on *equivalence transformations*. Specifically, the pair(s) (A, E) (and (F, D) , if $F \neq I$ and $D \neq I$) is (are) reduced to generalized real Schur form(s) (Golub and Van Loan 2013) by Schur decomposition(s) with orthogonal transformations, the right-hand side H is updated accordingly, the corresponding *reduced equation* (with matrices in Schur and triangular forms) is solved, and the result is transformed back to the solution of the original equation. For instance, for (2), the computations can be summarized as follows:

1. $\tilde{A} = Q^T A Z$, $\tilde{E} = Q^T E Z$;
2. $\tilde{H} = Q^T H Q$;
3. Solve $\tilde{A} \tilde{X} \tilde{E}^T + \tilde{E} \tilde{X} \tilde{A}^T = -\tilde{H}$;
4. $X = Z \tilde{X} Z^T$.

The pair $(\tilde{A}, \tilde{E})$ is in a *generalized real Schur form* if $\tilde{A}$ is in a real Schur form, i.e., it is block upper triangular with 1×1 and 2×2 diagonal blocks, corresponding to the real and complex conjugate eigenvalues, and $\tilde{E}$ is upper triangular. The reduced Lyapunov equation at step 3 is solved by a special back substitution process. For standard Lyapunov equations, A is reduced to a real Schur form, $\tilde{A} = Q^T A Q$, and the rest of the procedure is similar, but with $Z = Q$. Many algorithmic and computational details for this case are given, for example, in Sima (1996).

If $X \in \mathbb{R}^{m \times n}$ in (1), then the transformation method requires a computational effort of $O(m^3 + n^3)$ for finding the solution. Similarly, solving Lyapunov equations of order n requires a $O(n^3)$ effort. It is worth mentioning that using the equivalence between these equations and linear systems obtained through Kronecker products, their solution would require $O(m^3 n^3)$ or $O(n^6)$ operations, respectively. But even transformation methods are too computationally demanding for large-order equations, with m , and/or n bigger than several thousands (with the current computing machines). For such equations, iterative algorithms are used for obtaining approximate solutions based on exploiting their low-rank structure and/or sparsity. See Simoncini (2016) and the references therein for more details.

Other linear matrix equations are systems of linear matrix equations involving two unknown matrices and referred to as the *generalized Sylvester system of equations* in Varga (2017), $AX + YF = -V$ and $EX + YG = -W$, or equations where the unknown matrix appears more than twice, $\sum_{i=1}^k A_i X D_i = -H$, $k > 2$; see, for instance, Simoncini (2016). Systems of linear matrix equations are encountered when simultaneously block-diagonalizing a pair of matrices.

Quadratic Matrix Equations

The most often encountered quadratic matrix equations in the control domain are the algebraic Riccati equations (AREs). This name is given after the Italian mathematician Count J. F. Riccati (1676–1754), who investigated a scalar version

of these equations. The numerical solution of AREs is an essential step in many computational methods for linear-quadratic and robust control, filtering, controller order reduction, inner-outer factorization, spectral factorization, and other applications. Let $A, E, Q \in \mathbb{R}^{n \times n}$, $B, L \in \mathbb{R}^{n \times m}$, $Q = Q^T$, and $R = R^T \in \mathbb{R}^{m \times m}$, with E assumed nonsingular. In a compact notation, the *generalized continuous-time ARE* (GCARE), with unknown $X = X^T \in \mathbb{R}^{n \times n}$, and R nonsingular, is defined by

$$A^T X E + E^T X A - \mathcal{L}(X) R^{-1} \mathcal{L}(X)^T + Q = 0, \\ \mathcal{L}(X) := L + E^T X B. \quad (10)$$

Similarly, the *generalized discrete-time ARE* (GDARE) is defined by

$$A^T X A - E^T X E - \hat{\mathcal{L}}(X) \hat{R}(X)^{-1} \hat{\mathcal{L}}(X)^T + Q = 0, \\ \hat{\mathcal{L}}(X) := L + A^T X B, \quad (11)$$

where $\hat{R}(X) := R + B^T X B$ is nonsingular.

Riccati equations can have infinitely many solutions, but in certain conditions, there is a unique solution, X_s , with special properties. Equation (10) is associated with an *optimal regulator problem* that requires to minimize, with respect to $u(t)$, $t \geq 0$, the following quadratic *performance index* in terms of the system state and control input,

$$\int_0^\infty \left(x(t)^T Q x(t) + 2x(t)^T L u(t) + u(t)^T R u(t) \right) dt, \quad (12)$$

subject to the dynamic constraint in (7), with initial condition $x(0) = x_0$. For (11), the integral is replaced by an infinite sum for $t = 0, 1, \dots$. Discrete-time AREs are important since many dynamic systems are modeled by difference equations. It is assumed that the given *weighting matrices* Q and R satisfy $Q \geq 0$, and $R > 0$, for (10), while $R \geq 0$, for (11). In practice, often Q and L are expressed as $C^T \hat{Q} C$ and $L = C^T \hat{L}$, respectively, where $C \in \mathbb{R}^{p \times n}$ is the output matrix of the system and C , $\hat{Q}$, and $\hat{L}$ are given.

By a proper selection of Q , L , and R , the closed-loop dynamics can be modified to achieve, for instance, a faster transient response.

The solution of the minimization problem for (12) is a *state-feedback control law*, $u(t) = -Kx(t)$, $t \geq 0$, where

$$K := R^{-1} \mathcal{L}(X_s)^T, \quad (13)$$

and $X_s \geq 0$ is a *stabilizing solution* of (10), that is, $\Lambda(A - BK, E) \subset \mathbb{C}_-$. The matrix K is the *optimal regulator gain*. The same results hold for the discrete-time optimal control, in which case K is given by the formula

$$K := \hat{R}(X_s)^{-1} \hat{\mathcal{L}}(X_s)^T. \quad (14)$$

Briefly speaking, these control laws achieve system stabilization and a trade-off between the regulation error and control effort.

The optimal estimation or filtering problem, for systems with Gaussian noise disturbances, can be solved as a *dual* of an optimal control problem, and its solution gives the minimum variance state estimate, based on the system input and output. Specifically, an optimal estimation problem involves the solution of a similar ARE with A and E replaced by A^T and E^T , respectively, and the *input matrix* B replaced by the transpose of the *output matrix* $C \in \mathbb{R}^{p \times n}$. The results of an optimal design are often better suited in practice than those found by other approaches. For instance, pole assignment may deliver too large gain matrices, producing high-magnitude inputs, which might not be acceptable. The H_∞ theory and robust control applications also resort to AREs, but with different coefficient matrices and optimization objective (Francis 1987).

There is a vast literature concerning the theory and numerical solution of AREs and their use for solving optimal control and estimation problems and other practical applications. Several monographs, for instance Bini et al. (2012), Lancaster and Rodman (1995), Mehrmann (1991), and Sima (1996), address various theoretical and practical results. Numerous numerical methods, either “direct” or iterative, have been proposed for solving AREs; see, for instance, Mehrmann

(1991), Sima (1996), and Van Dooren (1981). The first class includes the (generalized) Schur techniques or structure-exploiting (QR-like) methods, for instance, Benner et al. (2016). These techniques use the connection between an ARE and a structured – Hamiltonian, for GCARE, or symplectic, for GDARE – matrix or matrix pencil, of order $2n$ or $2n + m$. An orthonormal basis of the stable invariant (or deflating subspace) of this matrix (pencil) is computed using the iterative QR (QZ) algorithm (Golub and Van Loan 2013) or a structured variant. Under standard assumptions, such as stabilizability of the pair $(A - \lambda E, B)$ and detectability of the pair $(Q - LR^{-1}L^T, A - \lambda E)$, the stable subspace has dimension n , and there is a stabilizing solution X_s , $X_s \geq 0$, that can be easily computed using the subspace basis. The second class of methods has several categories, including matrix sign function techniques, Newton techniques, doubling algorithms, or recursive algorithms. There are also several software implementations, for example, in MATLAB® or in the SLICOT Library (Benner et al. 1999; Van Huffel et al. 2004).

Newton’s method is best used for iterative improvement of a solution, delivering the maximal possible accuracy when starting from a good approximate solution. Moreover, it may be preferred in implementing certain fault-tolerant or slowly varying systems, which require online controller updating; then, the previously computed ARE solution can be used for initialization. It is worth mentioning that Newton’s method has been applied for solving special classes of large-order AREs, using low-rank Cholesky factors of the solutions of the Lyapunov equations built during the iterative process. However, the specialized solvers require additional assumptions, namely, A is structured or sparse; the solution X has a small rank compared with n .

Summary and Future Directions

The main results concerning linear and quadratic matrix equations often encountered in control

theory and its applications have been briefly reviewed. General or special equations related to both continuous- and discrete-time linear time-invariant systems have been considered. The essential assumptions involved and the properties of the solutions and of the related results have been addressed. Various solution methods have been mentioned, and recommended methods have been highlighted.

Reliability, accuracy, and efficiency are essential practical issues that should be achieved by the solvers. The advances in numerical linear algebra and scientific computations together with the spectacular progress of the computing systems performance and of the associated software supported the developments of basic numerical tools for control-related applications.

Both linear and quadratic matrix equation solvers may benefit of an iterative improvement of a computed solution. This is best performed by solving a similar equation that has the residual matrix at each iteration in the right-hand side. The solution of this equation is added as a correction to the currently computed solution. Usually, two-three iterations are sufficient to achieve the limiting accuracy.

The order of the problems tractable with the current solvers for dense matrices is limited to a few thousands. Large-order problems are now, and will be, the focus of the actual and future research interest. Iterative projection methods and ADI methods continue to be investigated, based on the fact that the solution has a low rank in many applications. Such methods are used by Newton-based Riccati solvers that solve Lyapunov equations at each iteration. New developments for more general matrix equations, containing terms with a nonlinear function of X , or further improvements in solving matrix equations for periodic systems are also expected. More applications will benefit of these advances.

of the infinite population problem is given by the fundamental MFG Hamilton-Jacobi-Bellman (HJB) and Fokker-Planck-Kolmogorov (FPK) equations which are linked by the state distribution of a generic agent, otherwise known as the system's mean field.

Mean Field Games

Peter E. Caines

Department of Electrical and Computer Engineering, McGill University, Montreal, QC, Canada

Abstract

The notion of the infinite population limit of large population games where agents are realized by controlled stochastic dynamical systems is introduced. The theory of infinite population mean field games (MFGs) is then presented including the fundamental MFG equations. Proofs of the existence and uniqueness of Nash equilibrium solutions to the MFG equations are discussed, and systems possessing major agents along with the standard asymptotically negligible agents are introduced. A short bibliography is included.

Definition

Mean field game (MFG) theory studies the existence of Nash equilibria, together with the individual strategies which generate them, in games involving a large number of agents modelled by controlled stochastic dynamical systems. This is achieved by exploiting the relationship between the finite and corresponding infinite limit population problems. The solution

Introduction

Large population dynamical multi-agent competitive and cooperative phenomena occur in a wide range of designed and natural settings such as communication, environmental, epidemiological, transportation, and energy systems, and they underlie much economic and financial behavior. Analysis of such systems is intractable using the finite population game theoretic methods which have been developed for multi-agent control systems (see, e.g., Basar and Ho 1974; Ho 1980; Basar and Olsder 1995; Bensoussan and Frehse 1984). The continuum population game theoretic models of economics (Aumann and Shapley 1974; Neyman 2002) are static, as, in general, are the large population models employed in network games (Altman et al. 2002) and transportation analysis (Wardrop 1952; Haurie and Marcotte 1985; Correa and Stier-Moses 2010). However, dynamical (or sequential) stochastic games were analyzed in the continuum limit in the work of Jovanovic and Rosenthal (1988) and Bergin and Bernhardt (1992), where the fundamental mean field equilibrium appears in the form of a discrete time dynamic programming equation and an evolution equation for the population state distribution.

The mean field equations for the infinite limits of dynamical games with large but finite populations of asymptotically negligible agents originated in the work of Huang et al. (2003, 2006, 2007) (where the framework was called the Nash certainty equivalence principle) and independently in that of Lasry and Lions (2006a,b, 2007), where the now standard terminology of mean field games (MFG) was introduced. Independent of both of these, the closely related notion of oblivious equilibria for large population dynamic games was introduced

by Weintraub et al. (2005) in the framework of Markov decision processes (MDP).

One of the main results of MFG theory is that in large population stochastic dynamic games individual feedback strategies exist for which any given agent will be in a Nash equilibrium with respect to the pre-computable behavior of the mass of the other agents; this holds exactly in the asymptotic limit of an infinite population and with increasing accuracy for a finite population of agents using the infinite population feedback laws as the finite population size tends to infinity, a situation which is termed an ε -Nash equilibrium. This behavior is described by the solution to the infinite population MFG equations which are fundamental to the theory; they consist of (i) a parameterized family of HJB equations (in the nonuniform parameterized agent case) and (ii) a corresponding family of pairs of McKean-Vlasov (MV) FPK PDEs, where (i) and (ii) are linked by the probability distribution of the state of a generic agent, that is to say, the mean field. For each agent these yield (i) a Nash value of the game, (ii) the best response strategy for the agent, (iii) the agent's stochastic differential equation (SDE) (i.e., the MV SDE pathwise description), and (iv) the state distribution of such an agent (i.e., the MV FPK SDE for the parameterized individual).

Dynamical Agents

In the diffusion-based models of large population games, the state evolution of a collection of N agents A_i , $1 \leq i \leq N < \infty$, is specified by a set N of controlled stochastic differential equations (SDEs) which in the important linear case take the form

$$dx_i(t) = [F_i x_i(t) + G_i u_i]dt + D_i dw_i(t),$$

$$1 \leq i \leq N,$$

where $x_i \in \mathbb{R}^n$ is the state, $u_i \in \mathbb{R}^m$ the control input, and w_i the state Wiener process of the i th agent A_i , where $\{w_i, 1 \leq i \leq N\}$ is a collection of N independent standard Wiener processes

in $\mathbb{R}^r$ independent of all mutually independent initial conditions. For simplicity, throughout this entry, all collections of system initial conditions are taken to be independent with zero mean and to have uniformly bounded second moment.

A simplified form of the general case treated in Huang et al. (2007) and Nourian and Caines (2013) is given by the following set of controlled SDEs which for each agent A_i includes state coupling with all other agents.

$$dx_i(t) = \frac{1}{N} \sum_{j=1}^N f(t, x_i(t), u_i(t), x_j(t))dt$$

$$+ \sigma dw_i(t), \quad 1 \leq i \leq N,$$

where here, for the sake of simplicity, only the uniform (non-parameterized) generic agent case is presented. The dynamics of a generic agent in the infinite population limit of this system is then described by the following controlled MV stochastic differential equation

$$dx(t) = f[x(t), u(t), \mu_t]dt + \sigma dw(t),$$

where $f[x, u, \mu_t] = \int_{\mathbb{R}^n} f(x, u, y) \mu_t(dy)$, with the initial condition measure μ_0 specified, where $\mu_t(\cdot)$ denotes the state distribution of the population at $t \in [0, T]$. The dynamics used in the analysis in Lasry and Lions (2006a, b, 2007) and Cardaliaguet (2012) are of the form $dx_i(t) = u_i(t)dt + \sigma dw_i(t)$.

The dynamical evolution of the state x_i of the i -th agent A_i in the discrete time Markov decision process (MDP)-based formulation of the so-called anonymous sequential games (Jovanovic and Rosenthal 1988; Bergin and Bernhardt 1992; Weintraub et al. 2005) is described by a Markov state transition function, or kernel, of the form $P_{t+1} := P(x_i(t+1)|x_i(t), x_{-i}(t), u_i(t), P_t)$.

Agent Performance Functions

In the basic finite population linear-quadratic diffusion case, the agent A_i , $1 \leq i \leq N$, possesses a performance, or loss, function of the form

$$J_i^N(u_i, u_{-i}) \\ = E \int_0^T \{\|x_i(t) - m_N(t)\|_Q^2 + \|u_i(t)\|_R^2\} dt,$$

where we assume the cost coupling to be of the form $m_N(t) := (\overline{x_N(t)} + \eta)$, $\eta \in \mathbb{R}^n$, where u_{-i} denotes all agents' control laws except for that of the i th agent, $\overline{x_N}$ denotes the population average state $(1/N) \sum_{i=1}^N x_i$, and here and below the expectation is taken over an underlying sample space which carries all initial conditions and Wiener processes.

For the general nonlinear case introduced in the previous section, a corresponding finite population mean field loss function is

$$J_i^N(u_i; u_{-i}) := E \int_0^T \left((1/N) \sum_{j=1}^N l(t, x_i(t), u_i(t), x_j(t)) \right) dt, \quad 1 \leq i \leq N,$$

where L is the nonlinear state cost-coupling function. Setting $l[x, u, \mu_t] = \int_{\mathbb{R}} l(x, u, y) \mu_t(dy)$, the infinite population limit of this cost function for a generic individual agent A is given by

$$J(u, \mu) := E \int_0^T l[x(t), u(t), \mu_t] dt,$$

which is the general expression for the infinite population individual performance functions appearing in Huang et al. (2006) and Nourian and Caines (2013) and which includes those of Lasry and Lions (2006a, b, 2007) and Cardaliaguet (2012). $e^{-\rho t}$ discounted costs are employed for infinite time horizon performance functions (Huang et al. 2003, 2007), while the sample path limit of the long-range average is used for ergodic MFG problems (Lasry and Lions 2006a, 2007) and in the analysis of adaptive MFG systems (Kizilkale and Caines 2013).

The Existence of Equilibria

The objective of each agent is to find strategies (i.e., control laws) which are admissible with

respect to information and other constraints and which minimize its performance function. The resulting problem is necessarily game theoretic, and consequently central results of the topic concern the existence of Nash equilibria and their properties.

The basic linear-quadratic mean field problem has an explicit solution characterizing a Nash equilibrium (see Huang et al. 2003, 2007). Consider the scalar infinite time horizon discounted case, with nonuniform parameterized agents A_θ with parameter distribution $F(\theta)$, $\theta \in \mathcal{A}$, and dynamical parameters identified as $a_\theta := F_\theta$, $b_\theta := G_\theta$, $Q := 1$, $r := R$; then the equation scheme generating the MFG equilibrium solution takes the form:

$$\rho s_\theta = \frac{ds_\theta}{dt} + a_\theta s_\theta - \frac{b_\theta^2}{r} \Pi_\theta s_\theta - x^*,$$

$$\frac{d\bar{x}_\theta}{dt} = (a_\theta - \frac{b_\theta^2}{r} \Pi_\theta) \bar{x}_\theta - \frac{b_\theta^2}{r} s_\theta, \quad 0 \leq t < \infty,$$

$$\bar{x}(t) = \int_{\mathcal{A}} \bar{x}_\theta(t) dF(\theta),$$

$$x^*(t) = \gamma(\bar{x}(t) + \eta),$$

$$\rho \Pi_\theta = 2a_\theta \Pi_\theta - \frac{b_\theta^2}{r} \Pi_\theta + 1, \quad \Pi_\theta > 0,$$

Riccati Equation

where the control action of the generic parameterized agent A_θ is given by $u_\theta^0(t) = -\frac{b_\theta}{r} (\Pi_\theta x_a(t) + s_\theta(t))$, $0 \leq t < \infty$. u_θ^0 is the optimal tracking feedback law with respect to $x^*(t)$ which is an affine function of the mean field term $\bar{x}(t)$, and the mean with respect to the parameter distribution F of the $\theta \in \mathcal{A}$ parameterized state means of the agents. Subject to conditions for the MFG scheme to have a solution, each agent is necessarily in a Nash equilibrium, within all full information causal (i.e., non-anticipative) feedback laws, with respect to the remainder of the agents when these are employing the law u^0 .

It is an important feature of the best response control law u_a^0 that its form depends only on the parametric data of the entire set of agents and, at

any instant, it is a feedback function of only the state of the agent A_a itself and the deterministic mean field dependent offset s .

For the general nonlinear case, the MFG equations on $[0, T]$ are given by the linked equations for (i) the performance function V for each agent in the continuum, (ii) the FPK for the MV-SDE

for that agent, and (iii) the specification of the best response feedback law depending on the mean field measure μ_t , with density p_t , and the agent's state $x(t)$. In the uniform agent case, these take the following form:

The Mean Field Game (MV) HJB – (MV) FPK Equations

$$\begin{aligned}
 \text{[MV-HJB]} \quad & -\frac{\partial V(t, x)}{\partial t} = \inf_{u \in U} \left\{ f[x(t), u(t), \mu_t] \frac{\partial V(t, x)}{\partial x} + l[x(t), u(t), \mu_t] \right\} + \frac{\sigma^2}{2} \frac{\partial^2 V(t, x)}{\partial x^2} \\
 & V(T, x) = 0, \quad (t, x) \in [0, T] \times \mathbb{R} \\
 \text{[MV-FPK]} \quad & \frac{\partial p_t(t, x)}{\partial t} = -\frac{\partial \{f[x(t), u(t), \mu_t] p_t(t, x)\}}{\partial x} + \frac{\sigma^2}{2} \frac{\partial^2 p_t(t, x)}{\partial x^2} \\
 \text{[MV-BR]} \quad & u(t) = \varphi(t, x(t) | \mu_t), \quad (t, x) \in [0, T] \times \mathbb{R}
 \end{aligned}$$

The general nonlinear MFG problem is approached by different routes in, for instance, (Huang et al. 2006; Nourian and Caines 2013) and in, for instance, (Lasry and Lions 2006a, b, 2007; Cardaliaguet 2012), respectively. In the former, subject to technical conditions, an iterated contraction argument in Banach space establishes the existence and uniqueness of a solution to the HJB-(MV) FPK equations, while in the latter a Schauder fixed point argument gives the existence of a solution and a dissipativity condition on the Hamiltonian yields uniqueness. The solutions to the MFG equations give the individual agents' best response control laws which necessarily yield Nash equilibria within all causal feedback laws for the infinite population problem. In Lasry and Lions (2006a, 2007), the MFG equations on the infinite time interval (i.e., the ergodic case) are obtained, while in the expository notes (Cardaliaguet 2012) the analytic properties of solutions to the HJB-FPK equations on the finite interval are analyzed using PDE methods including the theory of viscosity solutions. A third method to establish the existence and uniqueness of solutions is the probabilistic method (Carmona and Delarue 2018) by which the so-called master equation which unifies the MFGHJB and MFGFPK equations is analyzed directly.

An important result in MFG theory is that the conditions which yield the existence and uniqueness of solutions to the MFG equations together with the corresponding agents' best response (BR) strategies are sufficient for those strategies to possess the ε -Nash property (see, e.g., Huang et al. 2003, 2006, 2007; Nourian and Caines 2013; Cardaliaguet 2012). Specifically, it is shown that for any $\varepsilon > 0$, there exists a population size N_ε such that for all larger populations the use of the infinite population BR feedback laws gives each agent a value to its performance function within ε of its infinite population Nash value.

A counterintuitive feature of these results is that, asymptotically in population size, observations of the states of rival agents in MFG systems are of vanishing value to any given agent; this is in contrast to the situation in single-agent optimal control theory where the value of observations on an agent's environment is in general positive. However, when there is a major agent present in the population (Huang 2010; Nguyen and Huang 2012), state estimation plays a role, and a sequence of papers beginning with (Caines and Kizilkale 2016; Sen and Caines 2016) establishes, in the linear and nonlinear cases, respectively, the existence of equilibria when the minor agents extend their states with their individual estimates of the major agent's state.

Current Developments

Mean field game research has been rapidly expanding in terms of its exposition and in terms of both the fundamental theory and its applications. In particular the monographs by Bensoussan et al. (2013), Gomes and Saude (2014), and Kolokolstov and Malafeyav, and the two-volume monograph by Carmona and Delarue (2018), have now appeared summarizing, systematizing, and providing foundations and examples for large parts of the field. Examples of recent work include that of Bardi and Feleqi (2016) on nonlinear elliptic PDE systems and mean field games; the monograph (Gomes et al. 2016) treating the regularity of solutions; robust MFG theory with applications in (Bauso 2016); applications in algorithmic trading in finance in (Casgrain and Jaimungal 2018); applications to demand management in electrical power distribution in (Kizilkale and Malhamé 2016); and the economics of energy production (Ludkovski and Sircar 2015).

Abstract

This chapter discusses mechanical design techniques and control approaches that can be used to achieve high speed and fine precision

control of micro- and nanoscale positioning systems. By carefully using these design considerations, undesirable effects such as thermal drift, mechanical resonances, and off-axis motion can be minimized. Additionally, control systems can be designed to improve the positioning capabilities in open-loop and closed-loop configurations, allowing for high-bandwidth motion control while minimizing nonlinearities, such as hysteresis, and detrimental external disturbances.

Introduction

Positioning systems have been of interest to engineers for several decades, with advances for achieving micro- and nanoscale motion occurring primarily with the advent of scanning probe microscopy (SPM) techniques in the 1980s (Binnig et al. 1982). Such improvements have allowed for the imaging of biological processes at the micron scale, precisely orienting of optic lenses, increasing information density in data storage systems, and reducing the scale of reliable manufacturing, among many other applications (Devasia et al. 2007). Positioning of tools at this scale is commonly achieved with piezoelectric ceramic actuators, but other methods including voice coil motors and custom electromagnetic actuators have been found effective as well. Measurements of output displacements can be made using strain sensors, capacitive sensors, or laser interferometers. A natural consequence of these potentially different application, actuator, and sensor combinations is to take efforts towards designing custom platforms which integrates all necessary components for particular instruments. A commonality across almost all of these applications is a desire to increase operation speed and the capable

Mechanical Design and Control for Speed and Precision, Fig. 1 General block diagram structure for precision positioning system, P , designed to track a desired trajectory, x_{des} . The total control effort, u_{tot} , is composed of the summation of feedforward, u_{ff} , and feedback, u_{fb} , inputs. The actual system output is represented by x

precision of the positioning system to expand its utility.

In practice, the speed and precision capabilities of a positioning system depend on several components, including the power electronics and data acquisition hardware. In the following, emphasis is placed on mechanical design techniques and control systems which allow for increased bandwidth and precision. A typical control system block diagram for a positioning system is illustrated in Fig. 1, where mechanical design affects the plant dynamics (P) and controller design impacts feedforward (C_{ff}) and feedback control (C_{fb}). Additionally, emphasis is being placed on piezoelectric actuators due to their ubiquity in precision positioners for the sake of brevity, but the techniques discussed herein still are practical for devices with alternative actuation methods.

Mechanical Design

The mechanical design necessary for precision positioning consists of incorporating the selected actuators and sensors into a single mechatronic system (Fantner et al. 2006). This process can also be utilized to shape the displacement of an uncontrolled positioner such that it better matches a desired behavior. For example, monolithic flexure mechanisms, shown in Fig. 2a1–a2, can be designed to amplify the stroke of piezoactuators or guide their direction of motion to minimize off-axis effects (Fleming and Leang 2014). Even though motion can be improved with

such mechanisms, other detrimental behaviors can be present if left unaccounted for. Some examples of these undesired effects include thermal drift in actuators and mechanical components, inertial forces and interferences from resonances, and off-axis motion of the positioner's displacement (referred to as runout). Efforts can be taken to minimize or eliminate these effects through careful mechanical design.

Thermal Drift

Materials expand and contract when they experience changes in temperature. While this may be inconsequential for some macroscale applications, positioning systems that operate with nanometer precision can find such behavior significantly impactful. For example, if a piece of 6021 aluminum that is only 4.5 cm in length is used as the housing material of a positioner, it will expand slightly more than one micron for each degree Celsius increase in temperature it experiences. A potential source of temperature change is through the repeated excitation of the positioner's actuators. For example, if an actuator is cycled with a repeating trajectory (such as a sawtooth signal), the actuator and material coincident to it may begin to heat and expand. The environment in which the positioning system is contained may also introduce temperature fluctuations for the entire positioning system.

Design approaches can be taken to mitigate the thermal drift effects on a positioning platform. Materials with very low thermal deformation properties, such as titanium or Invar, can be utilized in the composition of a positioner. From the first example above, simply changing the material to Super Invar reduces the expansion to 13.5 nm for every degree Celsius increase in temperature, keeping all other dimensions the same. Operating environments can be carefully controlled or selected such that thermal fluctuations are minimized, for example, through isolation chambers which can be purchased for SPM-type instruments. The thermal expansion experienced by a positioner can also be directed based on the positioner design itself. For example, a platform with three contact points of

Mechanical Design and Control for Speed and Precision, Fig. 2 Examples of flexure mechanisms: (a1) motion-amplifying concept, (a2) motion-guiding concept,

and (b) an example positioning system with both amplifying and guiding flexure mechanisms (Nagel and Leang 2017)

constraint will experience out-of-plane bowing if all three points are fixed. By relaxing two of the constraints to be rolling contacts (supported by ball-type feet), then the device's expansion can be confined to planar motion, and the vertical drift will be substantially reduced.

Mechanical Resonances

The mechanical bandwidth of positioning systems is quantified by the first mechanical resonance in the direction of interest demonstrated by the device. However, resonant modes may be present in the housing or supporting structure of the positioner. For example, fastening hardware used to mount actuators can resonate at low and high frequencies and interfere with the output displacement. Furthermore, guiding mechanisms may introduce additional mechanical modes of oscillation before or near the primary resonance frequency of the overall positioning system. Another problem that arises from high-speed applications is due to inertial forces encountered with positioning actuators. The acceleration experienced by a sample platform displaced by an actuator increases proportionally with the frequency squared, resulting in quick increases in inertial forces that lead to excessive oscillations. The inertial force experienced on a piezoactuator

exhibiting sinusoidal motion at a frequency f is determined to be

$$F = 4\pi^2 m_{\text{eff}} \left(\frac{\Delta x}{2} \right) f^2, \quad (1)$$

where m_{eff} is the effective mass and Δx is the stroke length (Fleming and Leang 2014). These forces must be carefully managed to minimize damage to piezoelectric actuators and undesirable mechanical modes of vibration.

Flexure-guiding mechanisms are a standard design technique to mitigate the effects of mechanical resonances, as well as to increase the dominant mode of vibration for high-speed positioning. Additionally, they are employed to minimize runout. These compliant mechanisms can be approximated with spring-mass-damper models which consist of the effective inertia, stiffness, and damping of the device. For example, piezoelectric stack actuators are typically modeled as lightly damped second-order systems, and the first resonance (the natural frequency, ω_n) is defined from the equivalent mass and stiffness m_p and k_p ,

$$\omega_n = \sqrt{\frac{k_p}{m_p}}. \quad (2)$$

By introducing a guiding flexure mechanism to counteract the piezoactuator displacement, the nominal output of the actuator δ_0 is reduced through the addition of the flexure stiffness k_f added in parallel. The resultant output δ_f is then calculated to be

$$\delta_f = \delta_0 \frac{k_p}{k_p + k_f}. \quad (3)$$

Clearly, an infinitely stiff guiding flexure will result in no displacement. Although the displacement is reduced, the new equivalent stiffness can be increased greatly while the equivalent mass grows only slightly, thus increasing the first mechanical resonance frequency through Eq. (2). Applying this concept to off-axis directions, the stiffness in the off-axis directions can be increased such that their modes far exceed that of the primary actuation direction, eliminating their effects in the workable frequency range of the device.

Destructive forces experienced through high-frequency accelerations are typically addressed via preloading mechanisms. A compressive force is included on actuators in flexure-based mechanisms either through an additional loading mechanism (such as a finely threaded ball-ended screw) or by fitting the actuator into the flexure mechanism such that it naturally compresses the actuator when dormant (Yong et al. 2013). A maximum force can be approximated through Eq. (1) with known values for the actuator and target masses, as well as the maximum frequency that the device is expected to be operated at. By preloading the actuator such that it counteracts the expected inertial forces caused by the output accelerations, the forces experienced by the device's resonances can be effectively opposed.

Runout (Off-Axis Motion)

A majority of precision positioning systems will associate an input signal (e.g., voltage or current) with a desired direction of motion. Even multidirectional positioners typically have actuators oriented such that their displacements are independent of each other. However, positioning actuators will often have runout that degrade

performance. Even for the unidirectional positioner, this behavior can limit the speed capabilities of a positioning system and affect the precision of the device.

A simple solution to off-axis motion in positioners is to utilize flexure beams to guide displacements of an actuator in the direction of desired motion. Practitioners are usually satisfied if a design's dominant resonance frequency is in the desired direction of motion. In multi-axis designs, nesting actuators such that each layer is more compliant in their primary actuation direction (called a serial kinematic arrangement) allows for stiffness to be increased in the undesired directions (Kenton and Leang 2012). A consequence of such a configuration is the subsystems decreasing in speed for the outer positioners due to more effective mass being displaced. Decoupling mechanisms can be integrated into the body of a positioning system to mitigate parasitic motion for parallel-kinematic designs where actuators share the task of moving a target sample mass.

Motion Control

Once the mechanical design for a precision positioning system is established, a controller should be developed to further improve performance (Devasia et al. 2007). Choosing an adequate control architecture is essential for reducing tracking errors at higher frequencies, rejecting environmental disturbances, and mitigating nonlinear effects which may not be eliminated through mechanical design. Some examples of these nonlinearities include hysteresis (substantial in piezoelectric actuators), vibrational effects from high-order dynamics, creep, and off-axis interference for multidirectional positioners. Accounting for these issues is essential in achieving high-speed actuation while retaining high precision.

Control techniques that have been used for high-speed precision positioners can typically be categorized into two approaches, feedback and feedforward, as shown above in Fig. 1. Feedback techniques which rely on real-time sensor

information are preferable for removing errors and adding robustness to the overall system performance for precise and repeatable operation, while feedforward designs, typically based on system models, have been essential in pushing the speed capabilities of positioning platforms near or beyond the dominant mechanical resonance (Clayton et al. 2009).

High-Speed Trajectory Tracking

One main difficulty in achieving high-speed positioning is due to the lightly damped dynamics of the positioning system which are commonly present. High-frequency input signals (and even electrical noise) can excite these dominant resonance modes and cause undesired oscillations in the output position. Furthermore, because the dominant poles of the open-loop system are so close to the imaginary axis, closed-loop control can easily become unstable with higher control gains.

Despite the challenges with closed-loop stability, feedback control is the standard approach to controlling precision positioners. The standard controller is proportional-integral (PI) control, where the control input is given by

$$u(t) = K_p e(t) + K_i \int_0^t e(\tau) d\tau, \quad (4)$$

for constant proportional control gain K_p and integral control gain K_i . The tracking error is denoted by $e(t)$.

However, for lightly damped systems, this controller can be limited in bandwidth. A common approach that can improve PI control is to include a notch filter (or other inverse model-based filters) to attenuate the effects of the open-loop system resonances. By doing so, not only are these dynamics less susceptible to excitation, but the potential closed-loop bandwidth can be improved through an increased gain margin. However, small changes in the system dynamics (which can occur with changes in payload) reduce this techniques effectiveness and can lead to an unstable system. Other feedback methods can reduce the vibrational effects, including positive position feedback (PPF) and internal

resonance control (IRC). Robust controllers and techniques including sliding mode control (SMC), H_∞ , and loop-shaping have been shown to achieve high-speed closed-loop control, while repetitive errors can be reduced through learning techniques such as iterative learning control (ILC) and repetitive control (RC). In particular, the RC shown in Fig. 3 is designed to generate a discrete control effort based on a periodic error which repeats every N samples. This is done by tuning the low-pass filter

$$Q(z) = \frac{a}{z + b}, \quad (5)$$

where $|a| + |b| = 1$, along with phase-lead compensator $H(z) = z^m$, where m is a positive integer, and the RC gain, k_{RC} (Shan and Leang 2012). Such a controller is beneficial because it avoids the necessity to reset initial conditions for every cycle of the reference, which is the case for ILC.

A simple feedforward method for high-speed positioning is to actuate at the same frequency as the dominant resonance. High-speed positioning is achievable through this technique, but is practically limited to sinusoidal trajectories, and any excitation frequency higher or lower will experience poor performance, consequently. More recently, techniques to compute the control input ideal for a given system based on more general desired trajectories have been developed. One such method is based on optimal inversion (Croft et al. 1999), where a feedforward control input for a desired position trajectory of an actuator can be computed off-line based on the optimal inversion of the system's dynamics. Input shaping and trajectory redesign approaches have also been demonstrated to help achieve fast positioning (Boeren et al. 2014).

Dealing with Hysteresis

Hysteresis is a common issue present in piezoelectric materials and thus is frequently encountered in precision positioning. Cycling the input voltage of a piezoelectric device does not result in a linear relationship between voltage and position, but rather all previous input information,

Mechanical Design and Control for Speed and Precision, Fig. 3 Conventional repetitive control structure, designed to compensate for periodic trajectories

Mechanical Design and Control for Speed and Precision, Fig. 4 Hysteresis modeling: (a) hysteresis loop observed from cyclic input, (b) Hammerstein-Wiener structure cascading nonlinear hysteresis effects with linear

dynamics, and (c) variety of rate-dependent and rate-independent hysteresis models used in literature, based on Gan and Zhang (2019)

or its history of inputs, dictates how much the actuator will displace. Periodic trajectories result in hysteresis loops, an example of which is shown in Fig. 4a. This effect can lead to closed-loop instability for controllers and reduce the repeatability of a positioner if left unaccounted for. It should be noted that controlling the charge of a piezoactuator circumvents hysteretic behavior, but this is less commonly implemented, and controller designs should still be considered.

A large amount of research has been dedicated to removing hysteresis from positioning devices, with both feedback and feedforward approaches being successfully implemented. Feedback techniques include proportional-integral-derivative (PID) control, the more robust control methods mentioned above, and iterative methods like ILC and RC to correct for repeating errors in periodic reference trajectories. Robust methods such as H_∞ controllers also reduce the effects of hysteresis.

Feedforward methods typically exploit some model of the hysteresis behavior, which can be modeled in a Hammerstein-Wiener model structure: a cascade combination of a nonlinear operator with the system's linear dynamics, as shown in Fig. 4b. Modeling of this hysteretic effect can be achieved either through physics-based or phenomenological models, detailed in Fig. 4c, such as polynomial-based, Preisach, Prandtl-Ishlinskii, Bouc-Wen, and Jiles-Atherton models (Yong et al. 2013; Gan and Zhang 2019). Furthermore, these models vary in their handling of the hysteresis phenomena as either a rate-dependent operator or as a nonlinear effect that is independent of the input frequency. Once the observed hysteresis is modeled, steps can then be taken to determine an effective compensation method, usually through some form of model inversion, to effectively linearize the positioning output.

Disturbance Rejection

As with any general control problem, interferences can appear in the output of a positioner, either through environmental effects or interactions with other subsystems (e.g., multi-axis coupling). Acoustic signals, structural vibrations from buildings, and electrical noise from power-line sources can all affect positioners and degrade their performance. While some of these disturbances can be mitigated through mechanical designs and deployment considerations, for example, with vibration isolation tables and acoustic isolation chambers, it can be difficult to completely eliminate their effects. Therefore controllers that compensate for known and unknown disturbances are quintessential to high-speed and precise positioning in practical environments.

Robust feedback control has been essential in removing disturbance effects, starting with standard PI controllers. Compensators that are designed using the H_∞ approach have been very successful in countering a wide variety of interferences. Sliding mode controllers have also been used for general disturbance rejection (Wang and Xu 2018). Feedforward techniques are less common because such interferences are usually unmodeled or independent of normal operation. However, in the cases where knowledge of the interference origin can be determined, feedforward methods can be used to counteract their effects. Inversion methods can be used on models of the disturbance phenomena, such as coupling in multi-axis applications (Tien et al. 2005) or acoustic sources (Yi et al. 2018). The feedforward effort can be precomputed for repetitive errors, such as through ILC (Wu et al. 2009), or implemented in real time with finite impulse response representations.

Summary and Future Directions

Flexure-guided positioning stages have been heavily explored for precision positioning applications for over several decades and have been instrumental in achieving high-speed capabilities in a variety of fields, including nanotechnology. Through the careful design of such systems,

hindering effects can be reduced or eliminated. Control techniques can be deployed to achieve fast positioning, where a variety of feedback and feedforward methods have been shown to improve the system's speed and robustness.

New positioning system designs are actively being explored to expand on their effectiveness and utility. Integrating actuation and sensing components into a single monolithic design, such as microelectromechanical systems (MEMS) devices, and composing the entire positioning device from a material serving as the actuation method have shown potential as a means for improved precision, bandwidth, and versatility in positioners (Maroufi et al. 2018). Even more, additive manufacturing with metallic materials has expanded the achievable structures which can be developed as well as reduced manufacturing time. Multiple actuators of varying ranges and speeds are also being integrated into designs so as to allow for improved bandwidth and precision without sacrificing range capabilities (Bozchalooi et al. 2016). The increase in data storage and acquisition hardware speed has allowed for more information intensive techniques for control as well, including the use of machine learning to mitigate nonlinearities (Cheng et al. 2015). These emerging techniques may prove to be beneficial to industrial implementation of high-speed and precise products.

Mechanism Design

Ramesh Johari

Stanford University, Stanford, CA, USA

Abstract

Mechanism design is concerned with the design of strategic environments to achieve desired outcomes at equilibria of the resulting game. We briefly overview central ideas in mechanism design. We survey both objectives the mechanism designer may seek to achieve and equilibrium concepts the designer may use to model agents. We conclude by discussing a seminal example of mechanism design at work: the Vickrey-Clarke-Groves (VCG) mechanisms.

Keywords

Game theory · Incentive compatibility · Mechanism design

Introduction

Informally, *mechanism design* might be considered “inverse game theory.” In mechanism design, a principal (the “designer”) creates a system (the “mechanism”) in which strategic agents interact with each other. Typically, the goal of the mechanism designer is to ensure that at an “equilibrium” of the resulting strategic interaction, a “desirable” outcome is achieved. Examples of mechanism design at work include the following:

1. The FCC chooses to auction spectrum among multiple competing, strategic bidders to maximize the revenue generated. How should the FCC design the auction?
2. A search engine decides to run a market for sponsored search advertising. How should the market be designed?
3. The local highway authority decides to charge tolls for certain roads to reduce congestion. How should the tolls be chosen?

In each case, the mechanism designer is shaping the incentives of participants in the system. The mechanism designer must first define the desired objective and then choose a mechanism that optimizes that objective given a prediction of how strategic agents will respond. The theory of mechanism design provides guidance in solving such optimization problems.

We provide a brief overview of some central concepts in mechanism design. In the first section, we delve into more detail on the structure of the optimization problem that a mechanism designer solves. In particular, we discuss two central features of this problem: (1) What is the objective that the mechanism designer seeks to achieve or optimize? (2) How does the mechanism designer model the agents, i.e., what equilibrium concept describes their strategic interactions? In the second section, we study a specific celebrated class of mechanisms, the Vickrey-Clarke-Groves mechanisms.

Objectives and Equilibria

A mechanism design problem requires two essential inputs, as described in the introduction. First, what is the objective the mechanism designer is trying to achieve or optimize? And second, what are the constraints within which the mechanism designer operates? On the latter question, perhaps the biggest “constraint” in mechanism design is that the agents are assumed to act rationally in response to whatever mechanism is imposed on them. In other words, the mechanism designer needs to model *how* the agents will interact with each other. Mathematically, this is modeled by

a choice of equilibrium concept. For simplicity, we focus only on *static* mechanism design, i.e., mechanism design for settings where all agents act simultaneously.

Objectives

In this section we briefly discuss three objectives the mechanism designer may choose to optimize for: *efficiency*, *revenue*, and a *fairness* criterion.

1. **Efficiency** When the mechanism designer focuses on “efficiency,” they are interested in ensuring that the equilibrium outcome of the game they create is a Pareto efficient outcome. In other words, at an equilibrium of the game, there should be no individual that can be made strictly better off while leaving all others at least as well off as they were before. The most important instantiation of the efficiency criterion arises in *quasilinear* settings, i.e., settings where the utility of all agents is measured in a common, transferable monetary unit. In this case, it can be shown that achieving efficient outcomes is equivalent to maximizing the aggregate utility of all agents in the system. See Chap. 23 in Mas-Colell et al. (1995) for more details on mechanism design for efficient outcomes.
2. **Revenue** Efficiency may be a reasonable goal for an impartial social planner; on the other hand, in many applied settings, the mechanism designer is often herself a profit-maximizing party. In these cases, it is commonly the goal of the mechanism designer to maximize her own payoff from the mechanism itself.

A common example of this scenario is in the design of *optimal auctions*. An auction is a mechanism for the sale of a good (or multiple goods) among many competing buyers. When the principal is self-interested, she may wish to choose the auction design that maximizes her revenue from sale; the celebrated paper of Myerson (1981) studies this problem in detail.
3. **Fairness** Finally, in many settings, the mechanism designer may be interested more in achieving a “fair” outcome – even if such

an outcome is potentially not Pareto efficient. Fairness is subjective, and therefore, there are many potential objectives that might be viewed as fair by the mechanism designer. One common setting where the mechanism design strives for fair outcomes is in *cost sharing*: in a canonical example, the cost of a project must be shared “fairly” among many participants. See Chap. 15 of Nisan et al. (2007) for more discussion of such mechanisms.

Equilibrium Concepts

In this section we briefly discuss a range of equilibrium concepts the mechanism designer might use to model the behavior of players. From an optimization viewpoint, mechanism design should be viewed as maximization of the designer’s objective, subject to an equilibrium constraint. The equilibrium concept used captures the mechanism designer’s judgment about how the agents can be expected to interact with each other, once the mechanism designer has fixed the mechanism. Here we briefly discuss three possible equilibrium concepts that might be used by the mechanism designer.

1. **Dominant strategies** In dominant strategy implementation, the mechanism designer assumes that agents will play a (weak or strict) dominant strategy against their competitors. This equilibrium concept is obviously quite strong, as dominant strategies may not exist in general. However, the advantage is that when the mechanism possesses dominant strategies for each player, the prediction of play is quite strong. The Vickrey-Clarke-Groves mechanisms described below are central in the theory of mechanism design with dominant strategies.
2. **Bayesian equilibrium** In a Bayesian equilibrium, agents optimize given a common prior distribution about the other agents’ preferences. In Bayesian mechanism design, the mechanism designer chooses a mechanism taking into account that the agents will play according to a Bayesian equilibrium of the resulting game. This solution concept allows

the designer to capture a lack of complete information among players but typically allows for a richer family of mechanisms than mechanism design with dominant strategies. Myerson’s work on optimal auction design is carried out in a Bayesian framework (Myerson 1981).

3. **Nash equilibrium** Finally, in a setting where the mechanism designer believes the agents will be quite knowledgeable about each other’s preferences, it may be reasonable to assume they will play a Nash equilibrium of the resulting game. Note that in this case, it is typically assumed the designer does not know the utilities of agents at the time the mechanism is chosen – even though agents *do* know their own utilities at the time the resulting game is actually played. See, e.g., Moore (1992) for an overview of mechanism design with Nash equilibrium as the solution concept.

The Vickrey-Clarke-Groves Mechanisms

In this section, we describe a seminal example of mechanism design at work: the *Vickrey-Clarke-Groves* (VCG) class of mechanisms. The key insight behind VCG mechanisms is that by structuring payment rules correctly, individuals can be incentivized to truthfully declare their utility functions to the market and in turn achieve an efficient allocation. VCG mechanisms are an example of mechanism design with dominant strategies and with the goal of welfare maximization, i.e., efficiency. The presentation here is based on the material in Chap. 5 of Berry and Johari (2011), and the reader is referred there for further discussion. See also Vickrey (1961), Clarke (1971), and Groves (1973) for the original papers discussing this class of mechanisms.

To illustrate the principle behind VCG mechanisms, consider a simple example where we allocate a single resource of unit capacity among R competing users. Each user’s utility is measured in terms of a common currency unit; in particular, if the allocated amount is x_r and the payment to user r is t_r , then her utility is $U_r(x_r) + t_r$; we

refer to U_r as the *valuation* function, and let the space of valuation functions be denoted by $\mathcal{U}$. For simplicity we assume the valuation functions are continuous. In line with our discussion of efficiency above, it can be shown that the Pareto efficient allocation is obtained by solving the following:

$$\text{maximize } \sum_r U_r(x_r) \quad (1)$$

$$\text{subject to } \sum_r x_r \leq 1; \quad (2)$$

$$\mathbf{x} \geq 0. \quad (3)$$

However, achieving the efficient allocation requires knowledge of the utility functions; what can we do if these are unknown? The key insight is to make each user act *as if* they are optimizing the aggregate utility, by structuring payments appropriately. The basic approach in a VCG mechanism is to let the strategy space of each user r be the set $\mathcal{U}$ of possible valuation functions and make a payment t_r to user r so that her net payoff has the same form as the social objective (1). In particular, note that if user r receives an allocation x_r and a payment t_r , the payoff to user r is

$$U_r(x_r) + t_r.$$

On the other hand, the social objective (1) can be written as

$$U_r(x_r) + \sum_{s \neq r} U_s(x_s).$$

Comparing the preceding two expressions, the most natural means to align user objectives with the social planner's objectives is to *define the payment t_r as the sum of the valuations of all users other than r .*

A VCG mechanism first asks each user to declare a valuation function. For each r , we use $\hat{U}_r$ to denote the declared valuation function of user r and use $\hat{\mathbf{U}} = (\hat{U}_1, \dots, \hat{U}_R)$ to denote the vector of declared valuations. Formally, given a vector of declared valuation functions $\hat{\mathbf{U}}$, a VCG mechanism chooses the allocation $\mathbf{x}(\hat{\mathbf{U}})$ as an optimal solution to (1), (2), and (3) given $\hat{\mathbf{U}}$, i.e.,

$$\mathbf{x}(\hat{\mathbf{U}}) \in \arg \max_{\mathbf{x} \geq 0: \sum_r x_r \leq 1} \sum_r \hat{U}_r(x_r). \quad (4)$$

The payments are then structured so that

$$t_r(\hat{\mathbf{U}}) = \sum_{s \neq r} \hat{U}_s(x_s(\hat{\mathbf{U}})) + h_r(\hat{\mathbf{U}}_{-r}). \quad (5)$$

Here h_r is an arbitrary function of the declared valuation functions of users other than r , and various definitions of h_r give rise to variants of the VCG mechanisms. Since user r cannot affect this term through the choice of $\hat{U}_r$, she chooses $\hat{U}_r$ to maximize

$$U_r(x_r(\hat{\mathbf{U}})) + \sum_{s \neq r} \hat{U}_s(x_s(\hat{\mathbf{U}})).$$

Now note that given $\hat{\mathbf{U}}_{-r}$, the above expression is bounded above by

$$\max_{\mathbf{x} \geq 0: \sum_r x_r \leq 1} \left[U_r(x_r) + \sum_{s \neq r} \hat{U}_s(x_s) \right].$$

But since $\mathbf{x}(\hat{\mathbf{U}})$ satisfies (4), user r can achieve the preceding maximum by truthfully declaring $\hat{U}_r = U_r$. Since this optimal strategy does not depend on the valuation functions ($\hat{U}_s, s \neq r$) declared by the other users, we recover the important fact that in a VCG mechanism, *truthful declaration is a weak dominant strategy for user r .*

For our purposes, the interesting feature of the VCG mechanism is that it elicits the true utilities from the users and in turn (because of the definition of $\mathbf{x}(\hat{\mathbf{U}})$) chooses an efficient allocation. The feature that truthfulness is a dominant strategy is known as *incentive compatibility*: the individual incentives of users are aligned, or “compatible,” with overall efficiency of the system. The VCG mechanism achieves this by effectively paying each agent to tell the truth. The significance of the approach is that this payment can be properly structured even if the resource manager does not have prior knowledge of the true valuation functions.

Summary and Future Directions

Mechanism design provides an overarching framework for the “engineering” of economic systems. However, many significant challenges remain. First, VCG mechanisms are not computationally tractable in complex settings, e.g., combinatorial auctions; finding computationally tractable yet efficient mechanisms is a very active area of current research. Second, VCG mechanisms optimize for overall welfare, rather than revenue, and finding simple mechanisms that maximize revenue also presents new challenges. Finally, we have only considered implementation in static environments. Most practical mechanism design settings are dynamic. Dynamic mechanism design remains an active area of fruitful research.

Medical Cyber-Physical Systems: Challenges and Future Directions

Insup Lee, Oleg Sokolsky, and James Weimer
University of Pennsylvania, Philadelphia, PA,
USA

Abstract

This entry considers the area of medical cyber-physical systems, which recently has enjoyed much research and development efforts. We present a brief summary of recent developments, followed by a discussion of remaining challenges and directions for further development.

Keywords

Medical cyber-physical systems · Physiology modeling · Closed-loop treatments · Safety assurance

Introduction

One of the main characteristics of clinical practice is that it traditionally relies primarily on clinician’s expertise and direct interaction with the patient. Clinicians interpret observations from multiple sensors to evaluate the state of patient’s health and then decide on adjustments in treatment. This mode of operation has not fundamentally changed in recent times. What has changed is the workload of a typical clinician. Doctors and nurses are overworked. Moreover, recent improvement in technologies has given us new sensors that provide additional sources of information on the patient, all of which needs to be taken into account, further adding to the workload. This has raised concerns that clinician’s overload and “alarm fatigue” may result in reduced personal attention to each patient, potentially impacting the quality of decisions and treatment outcomes.

The key idea behind medical cyber-physical systems (MCPS) is that they can address these

concerns by providing computer-controlled automation. Such automation can monitor patient state by fusing data from multiple sensors and use this information in two complementary ways, as illustrated in Fig. 1. On the one hand, the system can leverage a model of patient's physiology to provide automatic closed-loop control of the treatment process, which does not require clinician's intervention most of the time. On the other hand, data-driven and machine learning techniques, needed for personalization of MCPS, require new approaches to safety and fairness verification. Note that the clinician normally has additional sources of information about the patient and can intervene with the treatment directly.

For MCPS to have a significant positive impact on clinician's workload and treatment outcomes, MCPS developers must overcome a variety of challenges. These challenges related to constructing models of patient physiology that are suitable for both closed-loop control and decision support; anomaly detection techniques that alert clinicians when human intervention is necessary; and safety assurance for the automation in order to prevent potential harm to the patient. In addition, modern MCPS are complex networked systems that can be affected by malicious external actors, both at the cyber and physical levels. Therefore, ensuring security and privacy is of paramount importance.

For the rest of the paper, we give a brief account of the state of the art in MCPS, followed by a discussion of the above challenges and future research directions.

State of the Art

Much of the work on closed-loop MCPS has concentrated on several conditions where patient's physiology is well understood and treatment effects are relatively isolated. Examples of closed-loop medical devices include automated drug infusion systems for analgesia (Derlien 1986; Liu and Northrop 1990; Cortes et al. 2008); control of blood pressure (Mason et al. 1985; Ruiz et al. 1993); control of blood

oxygenation (Iobbi et al. 2007; Morozoff and Smyth 2009) (and the related problem of control of sleep apnea (Yamashiro 2007)); control of epilepsy (Iasemidis et al. 2009; Salam et al. 2012) (and the related problem of anticipating and detecting seizures (Waterhouse 2003; Verma et al. 2011)); control of Parkinson's disease (Lawo and Herzog 2011); decision support for inpatient management of hyperglycemia (Davidson et al. 2005; Cochran et al. 2006; Juneja et al. 2007; Saager et al. 2008; Chase et al. 2011); telemedicine and decision support for treatment of insulin-dependent diabetes (Albisser 1989; Bott et al. 2007; Garcia-Saez et al. 2009); automated control of insulin-dependent diabetes (Patek et al. 2012; Cobelli et al. 2012; Breton et al. 2012; Percival et al. 2011; Steil et al. 2006; Weinzimer et al. 2008; Bruttomesso et al. 2009; Kovatchev et al. 2010; Hovorka et al. 2010; Dassau et al. 2010; Palerm 2011; Zisser et al. 2011; Atlas et al. 2010); pacemakers and other cardiac medical devices (Aseltine et al. 1979; Lai et al. 2009; Arzbacher et al. 2010; Jiang et al. 2011a,b; Shoaib et al. 2011; Jiang and Pajic 2012; Nirjon et al. 2012; Slepian et al. 2013); control of intracranial pressure (Rekate 1980); rehabilitation (Petrofsky et al. 1984; Lee et al. 1995; Stauffer et al. 2008; Pennycott et al. 2010; Nikitzuk et al. 2010); neural interfaces and prosthetics (Wu et al. 2004; Hatsopoulos et al. 2005; Weber et al. 2006; Marzullo et al. 2010; Emborg et al. 2011; Frankel et al. 2011; Simeral et al. 2011; Stanslaski et al. 2012; Witcher and Ellis 2012); force feedback in exoskeletal prostheses (Worsnopp et al. 2007; Wang et al. 2011); medical image acquisition (Harders and Szekely 2003); mechanical ventilation (Favre et al. 2003); and robotic surgical tools (Smith et al. 1991; Wyman et al. 1992; Sung and Gill 2001; Guodong et al. 2007; Penning et al. 2011; Turchetti et al. 2012; Hansen et al. 2012). From this long list of applications, it is clear that the medical establishment perceives a clear need for advanced treatment options. While the above MCPS address specific clinical needs, there remain several challenges to the design and analysis of safe, effective, and usable closed-loop MCPS.

Medical Cyber-Physical Systems: Challenges and Future Directions, Fig. 1 A typical MCPS involves two nested control loops. The automation may handle routine

treatment. The clinician would provide adjustments in response to anomalies in the treatment process, based on decision support provided by the automation

Challenges

Modeling patient physiology Design of closed-loop control typically requires a plant model. In the MCPS case, the “plant” is the patient being treated. Majority of today’s patient models are built in one of the two ways. Physiology-based models are credible, accurate, and generalizable, but too complex for real-time computation or for efficient design of closed-loop controllers. Specifically, they are often not amenable to existing techniques for model identification and parameter estimation. By contrast, data-based models are phenomenological black-box objects. They are simple and amenable to real-time computations and closed-loop control design, but cannot be used to explain what is happening with the patient. While simplicity and fidelity are important for control design, physiological transparency is critical for maintaining situational awareness by the caregiver, who should be able to tell when the treatment is not progressing as planned and intervene in an emergency. Therefore, finding the right balance between simplicity, fidelity, and physiological transparency is critical for rigorous design of closed-loop MCPS.

Understanding human-automation interactions Evaluation of safety and effectiveness of a closed-loop MCPS is impossible without a thorough understanding of how it will be used and how the operator – clinician or patient – will interact with the automation. Such interaction

takes the form of supervisory control, e.g., when a clinician changes the infusion pump rate, or the form of additional inputs to the controller that cannot be supplied by sensors, e.g., type 1 diabetes patients are typically expected to enter information about their meals. However, automation that requests frequent interactions (via alarms) with human operators, over time, can erode trust of operators in the system’s decision support and cause them to ignore recommendations. Many existing threshold-based bedside alarm systems are known to generate the large numbers of false positives, which has created the “alarm fatigue” problem, with clinicians ignoring alarms or completely shutting them off (Clark et al. 2007; Koppel et al. 2005; Weingart et al. 2003). Thus, automation needs to consider the quality of information provided by clinicians to produce feedback (e.g., alarms) that are highly specific and actionable. In doing so, automation can supply information to the operator to help make supervisory decisions, closing the outer control loop of the MCPS that directly includes the operator. User inputs such as meal intake records are often inaccurate and incomplete, and operators may misinterpret decision support information provided by the controller. Accurately capturing these human-automation interactions is key to the design and analysis of closed-loop MCPS.

Formal design of closed-loop systems with humans-in-the-loop Existing control design techniques are difficult to apply in the setting where both patient and operator exhibit complex

behaviors. There are several interrelated challenges that require us to develop new control design methods. First, limited observability of patient's physiology requires controllers to incorporate reliable detection of relevant physiological events based on available indirect observations. Second, control algorithms should allow personalization, which accounts for individual variation of physiology in different patients, as well as for different preferences for the levels of automation in operators. Third, the closed-loop system must be fair, in the sense that control performance minimizes nonclinical bias (e.g., race, gender, socioeconomic status). Finally, the physiological processes being controlled by MCPS are often distributed, taking the form of multiple hierarchical control loops.

Safety and fairness assurance Patient safety and fairness is one of the primary concerns in regulatory approval of MCPS. While the current generation MCPS primarily target a single physiological process, closed-loop MCPS targeting multiple physiological processes will need radical advances in safety analysis techniques due to inter/intra-patient variability and diversity of physiological responses. On the one hand, complexity of patient's physiological models that include complex parameter spaces will make most existing verification techniques impractical. On the other hand, as data-driven and machine learning techniques, that are needed for personalization of MCPS, require new approaches to safety and fairness verification. Furthermore, data-driven techniques need performance guarantees in diverse patient populations.

Security and privacy The safety of MCPS limits the ability to frequently update and patch MCPS. At the same time, many existing techniques for access control are impractical in the clinical setting and lead to work-arounds. Serious vulnerabilities have been found in many existing devices such as ICDs (Halperin et al. 2008) and insulin pumps (Radcliffe 2011; Advisory 2016; Raghunathan and Jha 2011; Paul et al. 2011). O'Keeffe et al. discuss vulnerabilities in AP systems in clinical trials (O'Keeffe et al. 2015). These vulnerabilities arise from failure to

implement well-known cryptographic solutions that leave the devices open to remote "hijacks," spoofing, or replay attacks. Recent attacks on insulin pumps suggest that manufacturers have been relatively slow in securing their systems (Advisory 2016). Solutions for low power encryption have been proposed (Beck et al. 2011), including for glucose sensors (Guan et al. 2011). Additionally, detailed threat assessments are needed to ensure that the system as a whole is secure and private (Kotz 2011).

Future Research Directions

The MCPS research community has been actively studying ways to address the challenges described above. Below, we discuss some of the open problems for MCPS.

Physiological modeling Common approaches to physiological modeling are based either on *maximal models*, first-principle models that accurately represent the underlying physiology (Cobelli and Carson 2008), or *minimal models*, simplified, phenomenological black-box models often based on compartmentalized techniques (Carson and Cobelli 2013). Maximal models are often unsuitable for data-driven modeling needed for personalization, or for existing control design approaches, due to their extreme complexity (Jacquez 1996; Godfrey 1983; Cobelli et al. 2009). By contrast, minimal models tend to be simpler and are suitable for data-driven modeling and control design. However, brute-force data-driven modeling techniques are often insensitive to interactions with the operator (e.g., manually delivered medications, equipment adjustments) and patient changes that are not recorded by sensors (e.g., getting out of bed, eating, exercising, etc.). Furthermore, data-driven minimal models tend to lack physiological transparency and are hard to be used for feedback to the operator. It may be possible to combine the benefits of the two modeling approaches. For example, in (Bighamian et al. 2018), the system model combines a control-theoretic model with a simple physics-based model and a phenomenological

model, balancing the overall simplicity of the model with physiological transparency.

Autonomous medical systems Most control algorithms for closed-loop MCPS referenced above involve single-input, single-output control loops and are designed using black-box data-driven models or models with locally linearized nonlinearities. Similar to autonomous vehicles, autonomous MCPS require human supervision. Existing work does not systematically address the hard problems of extreme variability of patient physiology and clinical interpretability, where, due to the severe observability constraints inherent in many MCPS, accurate adaptation to the complete patient physiology is impractical. In these scenarios, constraining adaptation by identifying and utilizing physiological invariants can enable safe and effective adaptation (Roederer et al. 2015; Weimer et al. 2016, 2017; Ivanov et al. 2015). While there has been recent work on incorporating physical invariants in vehicular systems, these technologies have not yet been applied to the medical domain.

Safety assurance and certification Formal methods have been used to verify MCPS in specific applications in limited scope (Jiang et al. 2012; Pajic et al. 2014; Abbas et al. 2016). Beyond these examples, there are emerging techniques for addressing complex physiological models (Chen et al. 2017) and modeling behavior of patients and clinicians (Chen et al. 2015). However, a methodology for safety assurance and certification in MCPS that integrates physiology and patient/operator behavior remains an active area of research.

Human factors in MCPS Given the central roles that humans play in closed-loop MCPS, interaction between humans and automation are central to the success of MCPS. While there is much work on human-automation interaction in other domains (e.g., aviation), in the health-care domain, this work has been mostly limited to the sociological context. A conceptual framework for clinicians interacting with AI-based automation has been laid out in Dermody and Fritz (2019). At the same time, security

and privacy of patient data remains an important topic to address in such systems. It is well-known that clinicians resort to a variety of work-arounds when they feel that automation prevents them from doing their work (Blythe et al. 2013; Koppel et al. 2008). Work-arounds can interfere with safety protections built into the automation system. For example, medication bar codes can be scanned after being detached from the medication container, allowing wrong medication to be administered (Koppel et al. 2008). Understanding the effects of human-automation interactions and corresponding work-arounds is essential for assuring safety and security of a system. However, such unanticipated interactions between operators and automation in clinical scenarios have not so far been considered in a rigorous modeling context.

Summary

MCPS is an actively evolving area of CPS research and development. It has a potential to enormously improve treatment procedures and health outcomes for many patients. However, complexity and diversity of human physiology, inherent roles of caregivers, technological resource constraints, as well as paramount safety, security, and privacy concerns make MCPS very challenging to build. In this entry, we discussed some of the more important challenges and promising research directions.

Model Building for Control System Synthesis

Marco Lovera and Francesco Casella
Politecnico di Milano, Milano, Italy

Abstract

The process of developing control-oriented mathematical models of physical systems is a complex task, which in general implies a careful combination of prior knowledge about the physics of the system under study with information coming from experimental data.

In this article the role of mathematical models in control system design and the problem of developing compact control-oriented models are discussed.

Keywords

Control-oriented modelling · Simulation · Continuous-time systems · Discrete-time systems · Time-invariant systems · Time-varying systems · Parameter-varying systems · Analytical models · Computational modelling · System identification · Uncertainty

Introduction

The design of automatic control systems requires the availability of some knowledge of the dynamics of the process to be controlled. In this respect, current methods for control system synthesis can be classified in two broad categories: model-free and model-based ones.

The former aim at designing (or tuning) controllers solely on the basis of experimental data collected directly on the plant, without resorting to mathematical models.

The latter, on the contrary, assume that suitable models of the plant to be controlled are available and rely on this information to work out control laws capable of meeting the design requirements.

While the research on model-free design methods is a very active field, the vast majority of control synthesis methods and tools fall in the model-based category and therefore assume that knowledge about the plant to be controlled is encoded in the form of dynamic models of the plant itself. Furthermore, in an increasing number of application areas, control system performance is becoming a key competitive factor for the success of innovative, high-tech systems. Consider, for example, high-performance mechatronic systems (such as robots), vehicles enhanced by active integrated stability, suspension and braking control, aerospace systems, and advanced energy conversion systems. All the

abovementioned applications possess at least one of the following features, which in turn call for accurate mathematical modelling for the design of the control system: closed-loop performance critically depends on the dynamic behavior of the plant; the system is made of many closely interacting subsystems; advanced control systems are required to obtain competitive performance, and these in turn depend on explicit mathematical models for their design; the system is safety critical and requires extensive validation of closed-loop stability and performance by simulation.

Therefore, building control-oriented mathematical models of physical systems is a crucial prerequisite to the design process itself (see, e.g., Lovera 2014 for a more detailed treatment of this topic).

In the following, two aspects related to modelling for control system synthesis will be discussed, namely, the role of models for control system synthesis and the actual process of model building itself.

The Role of Models for Control System Synthesis

Mathematical models play a number of different roles in the design of control systems. In particular, different classes of mathematical models are usually employed: *detailed*, high-fidelity, models for system simulation and *compact* models for control design. In this section the two model classes are presented, and their respective roles in the design of control systems are described. Note, in passing, that although hybrid system control is an interesting and emerging field, this paper will focus on purely continuous-time physical models, with application to the design of continuous-time or sampled-data control systems.

Detailed Models for System Simulation

Detailed models play a double role in the control design process. On one hand they allow checking how good (or crude) the compact model is, compared to a more detailed description, thus helping to develop good compact models. On the other

hand, they allow closed-loop performance verification of the controlled system, once a controller design is available (Indeed, verifying closed-loop performance using the same simplified model that was used for control system design is not a sound practice; conversely, verification performed with a more detailed model is usually deemed a good indicator of the control system performance, whenever experimental validation is not possible for some reason.).

Object-oriented modelling (OOM) methodologies and equation-based, object-oriented languages (EOOLs) provide very good support for the development of such high-fidelity models, thanks to equation-based modelling, acausal physical ports, hierarchical system composition, and inheritance. In particular, the Modelica language embeds these concepts and methodologies in an open standard, supported by a growing number of commercial and open-source tools; see Tiller (2001) and Fritzson (2014) for a comprehensive overview, and (Tiller 2019) for a quick introduction to the language. Any continuous-time EOOL model is equivalent to the set of differential-algebraic equations (DAEs) expressed in terms of the vector function F given by

$$F(x(t), \dot{x}(t), u(t), y(t), p, t) = 0, \quad (1)$$

where x is the vector of dynamic variables, u is the vector of input variables, y is the vector of algebraic variables, p is the vector of parameters, and t is the time.

It is interesting to highlight that the object-oriented approach (in particular, the use of replaceable components) allows defining and managing families of models of the same plant with different levels of complexity, by providing more or less detailed implementations of the same abstract interfaces. This feature of OOM allows the development of simulation models for different purposes and with different degrees of detail throughout the entire life of an engineering project, from preliminary design down to commissioning and personnel training, all within a coherent framework.

When focusing on control systems verification (and regardless of the actual control design methodology) once the controller has been set up, an OOM tool can be used to run closed-loop simulations, including both the plant and the controller model.

It is also possible to run such simulations within a computer-aided control system design (CACSD) environment that only supports causal plant models described by state-space equations (2). To this aim, one can use the model export facilities of OOM tools that automatically transform a detailed EOOL plant model featuring only causal top-level connectors (actuator input and sensor output signals) into a causal model. This is accomplished by reformulating (1) in state-space form (2), by means of symbolic and numerical transformations and then by generating executable code to compute the right-hand side of the state equations. The Functional Mock-up Interface (FMI) is a widely popular open standard enabling this kind of model exchange, see FMI Working Group (2014). As of the time of this writing, FMI is supported by over a hundred simulation and CACSD tools.

Finally, it is important to point out that physical model descriptions based on partial-differential equations (PDEs) can be handled in the OOM framework by means of discretization using finite volume, finite elements, or finite differences methods.

Compact Models for Control Design

The requirements for a control-oriented model can vary significantly from application to application. Design models can be tentatively classified in terms of two key features: complexity and accuracy. For a dynamic model, complexity can be measured in terms of its order; accuracy, on the other hand, can be measured using many different metrics (e.g., time-domain simulation or prediction error, frequency domain matching with the real plant, etc.) related to the capability of the model to reproduce the behavior of the true system in the operating conditions of interest.

Broadly speaking, it can be safely stated that the required level of closed-loop performance drives the requirements on the accuracy and

complexity of the design model. Similarly, it is intuitive that more complex models have the potential for being more accurate. So, one might be tempted to resort to very detailed mathematical representations of the plant to be controlled in order to maximize closed-loop performance. This consideration however is moderated by a number of additional requirements, which actually end up driving the control-oriented modelling process. First of all, present-day controller synthesis methods and tools have computational limitations in terms of the complexity of the mathematical models they can handle, so compact models representative of the dominant dynamics of the system under study are what is really needed. Furthermore, for many synthesis methods (such as, e.g., LQG or H_∞ synthesis), the complexity of the design model has an impact on the complexity of the controller, which in turn is constrained by implementation issues. Last but not least, in engineering projects the budget of the control-oriented modelling activity is usually quite limited, so the achievable level of accuracy is affected by this limitation.

It is clear from the above discussion that developing mathematical models suitable for control system synthesis is a nontrivial task but rather corresponds to the pursuit of a careful trade-off between complexity and accuracy. Furthermore, throughout the model development, one should keep in mind the eventual control application of the model, so its mathematical structure has to be compatible with currently available methods and tools for control system analysis and design.

Control-oriented models are usually formulated in state-space form:

$$\begin{aligned}\dot{x}(t) &= f(x(t), u(t), p, t) \\ y(t) &= g(x(t), u(t), p, t)\end{aligned}\quad (2)$$

where x is the vector of state variables, u is the vector of system inputs (control variables and disturbances), y is the vector of system outputs, p is the vector of parameters, and t is the continuous time. In the following, however, the focus will be on linear models, which constitute the starting point for most control law design methods and tools. In this respect, the main categories of

models used in control system synthesis can be defined as follows.

Linear Time-Invariant Models

Linear, time-invariant (LTI) models can be described in state-space form as

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t)\end{aligned}\quad (3)$$

or, equivalently, using an input–output model given by the (rational) transfer function matrix

$$G(s) = C(sI - A)^{-1}B + D, \quad (4)$$

where s denotes the Laplace variable. In many cases, the dynamics of systems in the form (2) in the neighborhood of an equilibrium (trim) point is approximated by (3) via analytical or numerical linearization; in this case, typically, u , x , and y represent the deviations of the variables with respect to the corresponding equilibrium values.

If, on the contrary, the control-oriented model is obtained by linearization of the DAE system (1), then a generalized LTI (or descriptor) model in the form

$$\begin{aligned}E\dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t)\end{aligned}\quad (5)$$

is obtained. Clearly, a generalized LTI model is equivalent to a conventional one as long as E is non-singular. The generalized form, however, encompasses the wider class of linearized plants with a singular E .

Linear Time-Varying Models

In some engineering applications, the need may arise to linearize the detailed model in the neighborhood of a trajectory rather than around an equilibrium point. Whenever this is the case, a linear, time-varying (LTV) model is obtained, in the form

$$\begin{aligned}\dot{x}(t) &= A(t)x(t) + B(t)u(t) \\ y(t) &= C(t)x(t) + D(t)u(t),\end{aligned}\quad (6)$$

where $A(t)$, $B(t)$, $C(t)$, and $D(t)$ are matrices and the entries of which are functions of time. An important subclass is the one of time-periodic behavior of the entries of the state-space matrices of the model, which corresponds to a linear time-periodic (LTP) model. LTP models arise when considering the linearization along periodic trajectories or, as it occurs in a number of engineering problems, whenever rotating systems are considered (e.g., spacecraft, rotorcraft, wind turbines). Finally, it is interesting to recall that (discrete-time) LTP models are needed to model multi-rate sampled-data systems.

Linear Parameter-Varying Models

The control-oriented modelling problem can be also formulated as the one of *simultaneously* representing all the linearizations of interest for control purposes of a given nonlinear plant. Indeed, in many control engineering applications, a single control system must be designed to guarantee the satisfactory closed-loop operation of a given plant in many different operating conditions (either in equilibria or along trajectories). Many design techniques are now available for this problem (see, e.g., Mohammadpour and Scherer 2012), provided that a suitable model in parameter-dependent form has been derived for the system to be controlled. Linear, parameter-varying (LPV) models described in state-space form as

$$\begin{aligned}\dot{x}(t) &= A(p(t))x(t) + B(p(t))u(t) \\ y(t) &= C(p(t))x(t) + D(p(t))u(t)\end{aligned}\quad (7)$$

are linear models the state-space matrices of which depend on a parameter vector p that can be time dependent. The elements of vector p may or may not be measurable, depending on the specific problem formulation. The present state-of-the-art of LPV modelling can be briefly summarized by defining two classes of approaches (see dos Santos et al. 2011 for details). *Analytical* methods are based on the availability of reliable nonlinear equations for the dynamics of the plant, from which suitable control-oriented representations can be derived (by resorting to, broadly speaking, suitable extensions of the familiar notion

of linearization, developed in order to take into account off-equilibrium operation of the system). *Experimental* methods are based entirely on identification, i.e., aimed at deriving LPV models for the plant directly from input–output data. In particular, some LPV identification techniques assume that one *global* identification experiment in which both the control input and the parameter vector are (persistently) excited in a simultaneous way, while others aim at deriving a parameter-dependent model on the basis of *local* experiments only, i.e., experiments in which the parameter vector is held constant and only the control input is excited.

Modern control theory provides methods and tools to deal with design problems in which stability and performance have to be guaranteed also in the presence of model uncertainty, both for regulation around a specified operating point and for gain-scheduled control system design. Therefore, modelling for control system synthesis should also provide methods to account for model uncertainty (both parametric and nonparametric) in the considered model class.

Most of the existing control design literature assumes that the plant model is given in the form of a linear fractional transformation (LFT) (see, e.g., Skogestad and Postlethwaite 2007 for an introduction to LFT modelling of uncertainty and Hecker et al. 2005 for a discussion of algorithms and software tools). LFT models consist of a feedback interconnection between a *nominal* LTI plant and a (usually norm-bounded) operator which represents model uncertainties, e.g., poorly known or time-varying parameters, nonlinearities, etc. A typical LFT interconnection is depicted in Fig. 1, where the nominal plant is denoted with P and the uncertainty block is denoted with Δ . The LFT formalism can be also used to provide a structured representation for the state-space form of LPV models, as depicted in Fig. 2, where the block $\Delta(\alpha)$ takes into account the presence of the uncertain parameter vector α , while the block $\Delta(p)$ models the effect of the varying operating point, parameterized by the vector of time-varying parameters p . Therefore, LFT models can be used for the design of robust and gain-scheduling controllers; in addition they

Model Building for Control System Synthesis, Fig. 1 Block diagram of the typical LFT interconnection adopted in the robust control framework

Model Building for Control System Synthesis, Fig. 2 Block diagram of the typical LFT interconnection adopted in the robust LPV control framework

can also serve as a basis for structured model identification techniques, where the uncertain parameters that appear in the feedback blocks are estimated based on input–output data sequences. The process of extracting uncertain/scheduling parameters from the design model of the system to be controlled is a highly complex one, in which symbolic techniques play a very important role. Tools already exist to perform this task (see, e.g., Hecker et al. 2005), while a recent overview of the state-of-the-art in this research area can be found in Hecker and Varga (2006).

Finally, it is important to point out that there is a vast body of advanced control techniques which are based on discrete-time models:

$$\begin{aligned} x(k+1) &= f(x(k), u(k), p, k) \\ y(k) &= g(x(k), u(k), p, k) \end{aligned} \quad (8)$$

where the integer time step k usually corresponds to multiples of a sampling period T_s . Many techniques are available to transform (2) into (8). Furthermore, LTI, LTV, and LPV models can be formulated in discrete time rather than in continuous time (see, e.g., Landau and Zito 2006 and Toth et al. 2012).

Building Models for Control System Synthesis

The development of control-oriented models of physical systems is a complex task, which in general implies a careful combination of prior knowledge about the physics of the system under study with information coming from experimental data. In particular, this process can follow very different paths depending on the type of information which is available on the plant to be controlled. Such paths are typically classified in the literature as follows (see, e.g., Ljung 2008 for a more detailed discussion).

White box modelling refers to the development of control-oriented models on the basis of first principles only. In this framework, one uses the available information on the plant to develop a detailed model using OOM or EOOL tools and subsequently works out a compact control-oriented model from it. If the adopted tool only supports simulation, then one can run simulations of the plant model, subject to suitably chosen excitation inputs (ranging from steps to persistently exciting input sequences such as, e.g., pseudorandom binary sequences and sine sweeps), and then reconstruct the dynamics by means of system identification methods. Note that in this way, the structure/order selection stage of the system identification process provides effective means to manage the complexity versus accuracy trade-off in the derivation of the compact model. A more direct approach, presently supported by many tools, is to directly compute the A, B, C, D matrices of the linearized system around specified equilibrium (trim) points, using symbolic or numerical linearization techniques. The result is usually a high-order linear system, which then can (sometimes must) be reduced to a low-order system by using model order reduction techniques (such as, e.g., balanced truncation). Model reduction techniques (see Antoulas 2009 for an in-depth treatment of this topic) allow to automatically obtain approximated compact models such as (3), starting from much more detailed simulation models, by formulating specific approximation bounds in

control-relevant terms (e.g., percentage errors of steady-state output values, norm-bounded additive or multiplicative errors of weighted transfer functions, or L_2 -norm errors of output transients in response to specified input signals).

Black box modelling, on the other hand, corresponds to situations in which the modelling activity is entirely based on input–output data collected on the plant (which therefore must be already available), possibly in dedicated, suitably designed, experiments (see Ljung 1999). Regardless of the type of model to be built (i.e., linear or nonlinear, time-invariant or time-varying, discrete-time or continuous time), the black box approach consists of a number of well-defined steps. First of all the structure of the model to be identified must be defined: in the linear time-invariant case, this corresponds to the choice of the number of poles and zeros for an input–output model or to the choice of model order for a state-space representation; in the nonlinear case, structure selection is a much more involved process in view of the much larger number of degrees of freedom which are potentially involved. Once a model structure has been defined, a suitable cost function to measure the model performance must be selected (e.g., time-domain simulation or prediction error, frequency domain model fitting, etc.), and the experiments to collect identification and validation data must be designed. Finally, the uncertain model parameters must be estimated from the available identification dataset, and the model must be validated on the validation dataset.

Gray box modelling (in various shades) corresponds to the many possible intermediate cases which can occur in practice, ranging from the white box approach to the black box one. As discussed in Ljung (2008), the critical issue in the development of an effective approach to control-oriented gray box modelling lies in the integration of existing methods and tools for physical systems modelling and simulation with methods and tools for parameter estimation. Such integration can take place in a number of different ways depending on the relative role of data and priors on the physics of the system in the specific application. A typical situation which occurs frequently in applications is when a white box model

(developed by means of OOM or EOOL tools) contains parameters having unknown or uncertain numerical values (such as, e.g., damping factors in structural models, aerodynamic coefficients in aircraft models and so on). Then, one may rely on input–output data collected in dedicated experiments on the real system to refine the white box model by estimating the parameters using the information provided by the data. This process is typically dependent on the specific application domain as the type of experiment, the number of measurements, and the estimation technique must meet application-specific constraints (as an example, see, e.g., Klein and Morelli 2006 for an overview of gray box modelling in aerospace applications and Tischler and Tobias 2016 for an overview of the “stitching” approach to LPV modelling using LTI identified models).

Summary and Future Directions

In this article the problem of model building for control system synthesis has been considered. An overview of the different uses of mathematical models in control system design has been provided, and the process of building compact control-oriented models starting from prior knowledge about the system or experimental data has been discussed. Present-day modelling and simulation tools support advanced control system design in a much more direct way. In particular, while methods and tools for the individual steps in the modelling process (such as OOM, linearization and model reduction, parameter estimation) are available, an integrated environment enabling the pursuit of all the abovementioned paths to the development of compact control-oriented models is still a subject for future development. The availability of such a tool might further promote the application of advanced, model-based techniques that are currently limited by the model development process.

Model Order Reduction: Techniques and Tools

Peter Benner¹ and Heike Faßbender²

¹Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany

²Institut Computational Mathematics, Technische Universität Braunschweig, Braunschweig, Germany

Abstract

Model order reduction is here understood as a computational technique to reduce the order of a dynamical system described by a set of ordinary or differential-algebraic equations to facilitate or enable its simulation, the design of a controller, or optimization and design of the physical system modeled. It focuses on representing the map from inputs into the system to its outputs, while its dynamics are treated as a black box so that the large-scale set of describing equations can be replaced by a much smaller set of analogous equations without sacrificing the accuracy of the input-output behavior.

Problem Description

This survey is concerned with linear time-invariant (LTI) systems in state-space form:

$$\begin{aligned} E\dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t), \end{aligned} \quad (1)$$

where $E, A \in \mathbb{R}^{n \times n}$ are the system matrices, $B \in \mathbb{R}^{n \times m}$ is the input matrix, $C \in \mathbb{R}^{p \times n}$ is the output matrix, and $D \in \mathbb{R}^{p \times m}$ is the feedthrough (or input-output) matrix. The size n of the matrix A is often referred to as the order of the LTI

system. It mainly determines the amount of time needed to simulate the LTI system.

Such LTI systems often arise from a finite element modeling using commercial software such as ANSYS or NASTRAN or from a space discretization of nonlinear partial differential equations followed by a suitable linearization. The number n of equations involved may range from a few hundred to a few million. Thus, solving (1) may become infeasible due to limitations on computational resources as well as growing inaccuracy due to numerical ill-conditioning. Model order reduction (MOR) seeks to replace (1) with a (much) smaller set of such equations so that the input-output behavior of both systems is similar in an appropriately defined sense.

The matrix E may be singular. In that case the first equation in (1) defines a system of differential-algebraic equations (DAEs); otherwise it is a system of ordinary differential equations (ODEs). For example, let $E = \begin{bmatrix} J & 0 \\ 0 & 0 \end{bmatrix}$ with a $j \times j$ nonsingular matrix J , $A = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}$ with the $j \times j$ matrix A_{11} and a nonsingular matrix A_{22} and $B = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix}$ with the $j \times m$ matrix B_1 . Partitioning the state vector $x(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}$ with $x_1(t)$ of length j , the DAE $E\dot{x}(t) = Ax(t) + Bu(t)$ splits into the set of algebraic equations $0 = A_{22}x_2(t) + B_2u(t)$ and the ODE

$$J\dot{x}_1(t) = A_{11}x_1(t) + (B_1 - A_{12}A_{22}^{-1}B_2)u(t).$$

For clarity of presentation, we focus in the following on systems of ODEs only. All techniques discussed in this survey can be generalized for systems of DAEs even if their structure is more complicated than in the case considered above; see Benner and Stykel (2017) for details. Moreover, to simplify the description, only continuous-time systems are considered here. The discrete-time case, i.e., when the first equation in (1) is a system of difference equations, can be treated mostly analogously; see, e.g., Antoulas (2005).

An alternative way to represent LTI systems is provided by the transfer function matrix (TFM), a matrix-valued function whose elements are rational functions. Assuming $x(0) = 0$ and tak-

ing Laplace transforms in (1) yield $sX(s) = AX(s) + BU(s)$, $Y(s) = CX(s) + DU(s)$, where $X(s)$, $Y(s)$, and $U(s)$ are the Laplace transforms of the time signals $x(t)$, $y(t)$, and $u(t)$, respectively. The map from inputs U to outputs Y is then described by $Y(s) = G(s)U(s)$ with the TFM

$$G(s) = C(sE - A)^{-1}B + D, \quad s \in \mathbb{C}. \quad (2)$$

The aim of MOR is to find an LTI system

$$\tilde{E}\dot{\tilde{x}}(t) = \tilde{A}\tilde{x}(t) + \tilde{B}u(t), \quad \tilde{y}(t) = \tilde{C}\tilde{x}(t) + \tilde{D}u(t) \quad (3)$$

of reduced order $r \ll n$ such that the corresponding TFM

$$\tilde{G}(s) = \tilde{C}(s\tilde{E} - \tilde{A})^{-1}\tilde{B} + \tilde{D} \quad (4)$$

approximates the original TFM (2). That is, using the same input $u(t)$ in (1) and (3), we want that the output $\tilde{y}(t)$ of the reduced-order model (ROM) (3) approximates the output $y(t)$ of (1) well enough for the application considered (e.g., controller design). In general, one requires $\|y(t) - \tilde{y}(t)\| \leq \varepsilon$ for all feasible inputs $u(t)$, for (almost) all t in the time domain of interest, and for a suitable norm $\|\cdot\|$. In control theory one often employs the $\mathcal{L}_2$ - or $\mathcal{L}_\infty$ -norms on $\mathbb{R}$ or $[0, \infty]$, respectively, to measure time signals or their Laplace transforms. In the situations considered here, the $\mathcal{L}_2$ -norms employed in frequency and time domain coincide due to the Paley-Wiener theorem (or Parseval's equation or the Plancherel theorem, respectively); see Antoulas (2005) and Zhou et al. (1996) for details. As $Y(s) - \tilde{Y}(s) = (G(s) - \tilde{G}(s))U(s)$, one can therefore consider the approximation error of the TFM $\|G(\cdot) - \tilde{G}(\cdot)\|$ measured in an induced norm instead of the error in the output $\|y(\cdot) - \tilde{y}(\cdot)\|$.

Depending on the choice of the norm, different MOR goals can be formulated. Typical choices are (see, e.g., Antoulas 2005 for a more thorough discussion)

- $\|G(\cdot) - \tilde{G}(\cdot)\|_{\mathcal{H}_\infty}$, where

$$\|F(\cdot)\|_{\mathcal{H}_\infty} = \sup_{s \in \mathbb{C}_+} \sigma_{\max}(F(s)).$$

Here, $\sigma_{\max}$ is the largest singular value of the matrix $F(s)$, and $\mathbb{C}_+$ denotes the open right half complex plane. This minimizes the maximal magnitude of the frequency response of the error system and by the Paley-Wiener theorem bounds the $\mathcal{L}_2$ -norm of the output error;

- $\|G(\cdot) - \tilde{G}(\cdot)\|_{\mathcal{H}_2}$, where (with $\iota = \sqrt{-1}$)

$$\|F(\cdot)\|_{\mathcal{H}_2}^2 = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \text{tr}(F(\iota\omega)^* F(\iota\omega)) d\omega.$$

This ensures a small error

$$\|y(\cdot) - \tilde{y}(\cdot)\|_{\mathcal{L}_\infty(0, \infty)} = \sup_{t > 0} \|y(t) - \tilde{y}(t)\|_\infty$$

(with $\|\cdot\|_\infty$ denoting the maximum norm of a vector) uniformly over all inputs $u(t)$ having bounded $\mathcal{L}_2$ -energy, that is, $\int_0^\infty u(t)^T u(t) dt \leq 1$; see Gugercin et al. (2008).

Besides a small approximation error, one may impose additional constraints for the ROM. One might require certain properties (such as stability and passivity) of the original system to be preserved. Rather than considering the full nonnegative real line in time domain or the full imaginary axis in frequency domain, one can also consider bounded intervals in both domains. For these variants, see, e.g., Antoulas (2005) and Obinata and Anderson (2001).

Methods

There are a number of different methods to construct ROMs; see, e.g., Antoulas (2005), Benner et al. (2005, 2017), Obinata and Anderson (2001), and Schilders et al. (2008). In this survey, we concentrate on projection-based methods which restrict the full state $x(t)$ to an r -dimensional subspace by choosing $\tilde{x}(t) = W^* x(t)$, where W is an $n \times r$ matrix. Here the conjugate transpose of a complex-valued matrix Z is denoted by Z^* , while the transpose of a matrix Y will be denoted by Y^T .

Choosing $V \in \mathbb{C}^{n \times r}$ such that $W^*V = I \in \mathbb{R}^{r \times r}$ yields an $n \times n$ projection matrix $\Pi = VW^*$ which projects onto the r -dimensional subspace spanned by the columns of V along the kernel of W^* . Applying this projection to (1), one obtains the reduced-order LTI system (3) with

$$\tilde{E} = W^*EV, \quad \tilde{A} = W^*AV, \quad \tilde{B} = W^*B, \quad \tilde{C} = CV \quad (5)$$

and an unchanged $\tilde{D} = D$. If $V = W$, Π is an orthogonal projector and is called a Galerkin projection. If $V \neq W$, Π is an oblique projector, sometimes called a Petrov-Galerkin projection.

In the following, we will briefly discuss the main classes of methods to construct suitable matrices V and W : truncation-based methods and interpolation-based methods. Other methods, in particular combinations of the two classes discussed here, can be found in the literature. In case the original LTI system is real, it is often desirable to construct a real ROM. All of the methods discussed in the following either do construct a real ROM or there is a variant of the method which does. In order to keep this exposition at a reasonable length, the reader is referred to the cited literature.

Truncation-Based Methods

The general idea of truncation is most easily explained by *modal truncation*: For simplicity, assume that $E = I$ and that A is diagonalizable, $T^{-1}AT = D_A = \text{diag}(\lambda_1, \dots, \lambda_n)$. Further we assume that the eigenvalues $\lambda_\ell \in \mathbb{C}$ of A can be ordered such that

$$\text{Re}(\lambda_n) \leq \text{Re}(\lambda_{n-1}) \leq \dots \leq \text{Re}(\lambda_1) < 0, \quad (6)$$

(i.e., all eigenvalues lie in the open left half complex plane). This implies that the system is stable. Let V be the $n \times r$ matrix consisting of the first r columns of T , and let W^* be the first r rows of T^{-1} , that is, $W = V(V^*V)^{-1}$. Applying the transformation T to the LTI system (1) yields

$$T^{-1}\dot{x}(t) = (T^{-1}AT)T^{-1}x(t) + (T^{-1}B)u(t) \quad (7)$$

$$y(t) = (CT)T^{-1}x(t) + Du(t) \quad (8)$$

with

$$T^{-1}AT = \begin{bmatrix} W^*AV & \\ & A_2 \end{bmatrix}, \quad T^{-1}B = \begin{bmatrix} W^*B \\ B_2 \end{bmatrix},$$

and $CT = [CV \ C_2]$, where

$$W^*AV = \text{diag}(\lambda_1, \dots, \lambda_r) \text{ and}$$

$A_2 = \text{diag}(\lambda_{r+1}, \dots, \lambda_n)$. Preserving the r dominant poles (eigenvalues with largest real parts) by truncating the rest (i.e., discarding A_2 , B_2 , and C_2 from (7)) yields the ROM as in (5). It can be shown that the error bound

$$\|G(\cdot) - \tilde{G}(\cdot)\|_{\mathcal{H}_\infty} \leq \|C_2\| \|B_2\| \frac{1}{|\text{Re}(\lambda_{r+1})|}$$

holds, e.g. (Benner 2006). As eigenvalues contain only limited information about the system, this is not necessarily a meaningful ROM. In particular, the dependence of the input-output relation on B and C is completely ignored. This can be enhanced by more refined dominance measures taking B and C into account; see, e.g., Varga (1995) and Benner et al. (2011).

More suitable ROMs can be obtained by *balanced truncation*. To introduce this concept, we no longer need to assume A to be diagonalizable, but we require the stability of A in the sense of (6). For simplicity, we assume $E = I$. Loosely speaking, a balanced representation of an LTI system is obtained by a change of coordinates such that the states which are hard to reach are at the same time those which are difficult to observe. This change of coordinates amounts to an equivalence transformation of the realization (A, B, C, D) of (1) called state-space transformation as in (7), where T now is the matrix representing the change of coordinates. The new system matrices $(T^{-1}AT, T^{-1}B, CT, D)$ form a balanced realization of (1). Truncating in this balanced realization the states that are hard to reach and difficult to observe results in a ROM.

Consider the Lyapunov equations

$$AP + PA^T + BB^T = 0, \quad A^T Q + QA + C^T C = 0. \quad (9)$$

The solution matrices P and Q are called controllability and observability Gramians, respectively. If both Gramians are positive definite, the LTI system is minimal. This will be assumed from hereon in this section.

In balanced coordinates the Gramians P and Q of a stable minimal LTI system satisfy $P = Q = \text{diag}(\sigma_1, \dots, \sigma_n)$ with the Hankel singular values $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n > 0$. The Hankel singular values are the positive square roots of the eigenvalues of the product of the Gramians PQ , $\sigma_k = \sqrt{\lambda_k(PQ)}$. They are system invariants, i.e., they are independent of the chosen realization of (1) as they are preserved under state-space transformations.

Given the minimal LTI system (1) in a non-balanced coordinate form and the Gramians P and Q satisfying (9), the transformation matrix T which yields an LTI system in balanced coordinates can be computed via the so-called square root algorithm as follows:

- Compute the Cholesky factors S and R of the Gramians such that $P = S^T S$, $Q = R^T R$.
- Compute the singular value decomposition of $SR^T = \Phi \Sigma \Gamma^T$, where Φ and Γ are orthogonal matrices and $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_n)$ is a diagonal matrix with the Hankel singular values σ_i , $i = 1, \dots, n$, ordered decreasingly on its diagonal. $T = S^T \Phi \Sigma^{-\frac{1}{2}}$ yields the balancing transformation (note that $T^{-1} = \Sigma^{\frac{1}{2}} \Phi^T S^{-T} = \Sigma^{-\frac{1}{2}} \Gamma^T R$).
- Partition Φ , Σ , Γ , T , T^{-1} into blocks of corresponding sizes

$$\Sigma = \begin{bmatrix} \Sigma_1 & \\ & \Sigma_2 \end{bmatrix}, \Phi = \begin{bmatrix} \Phi_1 \\ \Phi_2 \end{bmatrix}, \Gamma^T = \begin{bmatrix} \Gamma_1^T \\ \Gamma_2^T \end{bmatrix},$$

$$T = [V \ V_2], T^{-1} = \begin{bmatrix} W^T \\ W_2^T \end{bmatrix},$$

with $\Sigma_1 = \text{diag}(\sigma_1, \dots, \sigma_r)$ and apply T to (1) to obtain (7) with

$$T^{-1}AT = \begin{bmatrix} W^T AV & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

$$T^{-1}B = \begin{bmatrix} W^T B \\ B_2 \end{bmatrix}, CT = [CV \ C_2]. \quad (10)$$

Note that $W = R^T \Gamma_1 \Sigma_1^{-\frac{1}{2}}$ and $V = S^T \Phi_1 \Sigma_1^{-\frac{1}{2}}$. Preserving the r dominant Hankel singular values by truncating the rest yields the ROM as in (5).

As $W^T V = I$, balanced truncation is an oblique projection method. The ROM is stable with the Hankel singular values $\sigma_1, \dots, \sigma_r$. It can be shown that if $\sigma_r > \sigma_{r+1}$, the error bound

$$\|G(\cdot) - \tilde{G}(\cdot)\|_{\mathcal{H}_\infty} \leq 2 \sum_{k=r+1}^n \sigma_k \quad (11)$$

holds. Given an error tolerance, this allows to choose the appropriate order r of the ROM in the course of the computations.

As the explicit computation of the balancing transformation T is numerically hazardous, one usually uses the equivalent balancing-free square root algorithm (Varga 1991) in which orthogonal bases for the column spaces of V and W are computed. The so obtained ROM is no longer balanced but preserves all other properties (error bound, stability). Furthermore, it is shown in Benner et al. (2000) how to implement the balancing-free square root algorithm using low-rank approximations to S and R without ever having to resort to the square solution matrices P and Q of the Lyapunov equations (9). This yields an efficient algorithm for balanced truncation for LTI systems with large dense matrices. For systems with large-scale sparse A , efficient algorithms based on sparse solvers for (9) exist; see Benner (2006).

By replacing the solution matrices P and Q of (9) by other pairs of positive (semi-)definite matrices characterizing alternative controllability and observability related system information, one obtains a family of model reduction methods including stochastic/bounded-real/positive-real balanced truncation. These can be used if further properties like minimum phase, passivity, etc. are to be preserved in the ROM; for further details,

see Antoulas (2005) and Obinata and Anderson (2001).

The balanced truncation yields good approximation at high frequencies as $\tilde{G}(i\omega) \rightarrow G(i\omega)$ for $\omega \rightarrow \infty$ (as $\tilde{D} = D$), while the maximum error is often attained for $\omega = 0$. For a perfect match at zero and a good approximation for low frequencies, one may employ the *singular perturbation approximation* (SPA, also called balanced residualization). In view of (7) and (10), balanced truncation can be seen as partitioning $T^{-1}x$ according to (10) into $[x_1^T, x_2^T]^T$ and setting $x_2 \equiv 0$ implying $\dot{x}_2 \equiv 0$ as well. For SPA, one assumes that x_2 is in steady state, that is, $\dot{x}_2 \equiv 0$, such that

$$\begin{aligned}\dot{x}_1 &= W^T A V x_1 + A_{12} x_2 + W^T B u, \\ 0 &= A_{21} x_1 + A_{22} x_2 + B_2 u.\end{aligned}$$

Solving the second equation for x_2 and inserting it into the first equation yield

$$\begin{aligned}\dot{x}_1 &= \left(W^T A V - A_{12} A_{22}^{-1} A_{21} \right) x_1 \\ &\quad + \left(W^T B - A_{12} A_{22}^{-1} B_2 \right) u.\end{aligned}$$

For the output equation, it follows

$$\tilde{y} = \left(C V - C_2 A_{22}^{-1} A_{21} \right) x_1 + \left(D - C_2 A_{22}^{-1} B_2 \right) u.$$

This ROM makes use of the information in the matrices A_{12} , A_{21} , A_{22} , B_2 , and C_2 discarded by balanced truncation. It fulfills $\tilde{G}(0) = G(0)$ and the error bound (11); moreover, it preserves stability.

Besides SPA, another related truncation method that is not based on projection is *optimal Hankel norm approximation* (HNA). The description of HNA is technically quite involved; for details, see Zhou et al. (1996) and Glover (1984). It should be noted that the so obtained ROM usually has similar stability and accuracy properties as for balanced truncation.

Interpolation-Based Methods

Another family of methods for MOR is based on (rational) interpolation. The unifying feature of the methods in this family is that the original TFM (2) is approximated by a rational matrix function of lower degree satisfying some interpolation conditions (i.e., the original and the reduced-order TFM coincide, e.g., $G(s_0) = \tilde{G}(s_0)$ at some predefined value s_0 for which $A - s_0 E$ is nonsingular). Computationally this is usually realized by certain Krylov subspace methods.

The classical approach is known under the name of *moment-matching* or *Padé(-type) approximation*. In these methods, the transfer functions of the original and the ROMs are expanded into power series, and the ROM is then determined so that the first coefficients in the series expansions match. In this context, the coefficients of the power series are called moments, which explains the term “moment-matching”. One speaks of Padé-approximation if the number of matching moments is maximized for a given degree of the approximating rational function.

Classically, the expansion of the TFM (2) in a power series about an expansion point s_0

$$G(s) = \sum_{j=0}^{\infty} M_j(s_0)(s - s_0)^j \quad (12)$$

is used. The moments $M_j(s_0)$, $j = 0, 1, 2, \dots$, are given by

$$M_j(s_0) = -C [(A - s_0 E)^{-1} E]^j (A - s_0 E)^{-1} B.$$

Consider the (block) Krylov subspace

$$\mathcal{K}_k(F, H) = \text{span}\{H, FH, F^2H, \dots, F^{k-1}H\}$$

for $F = (A - s_0 E)^{-1} E$ and $H = -(A - s_0 E)^{-1} B$ with an appropriately chosen expansion point s_0 which may be real or complex. From the definitions of A , B , and E , it follows that $F \in \mathbb{K}^{n \times n}$ and $H \in \mathbb{K}^{n \times m}$, where $\mathbb{K} = \mathbb{R}$ or $\mathbb{K} = \mathbb{C}$ depending on whether s_0 is chosen in $\mathbb{R}$ or in $\mathbb{C}$. Considering $\mathcal{K}_k(F, H)$ column by column,

this leads to the observation that the number of column vectors in $\{H, FH, F^2H, \dots, F^{k-1}H\}$ is given by $r = m \cdot k$, as there are k blocks $F^jH \in \mathbb{K}^{n \times m}$, $j = 0, \dots, k-1$. In the case when all r column vectors are linearly independent, the dimension of the Krylov subspace $\mathcal{K}_k(F, H)$ is $m \cdot k$. Assume that a unitary basis for this block Krylov subspace is generated such that the column space of the resulting unitary matrix $V \in \mathbb{C}^{n \times r}$ spans $\mathcal{K}_k(F, G)$. Applying the Galerkin projection $\Pi = VV^*$ to (1) yields a ROM whose TFM satisfies the following (Hermite) interpolation conditions at s_0 :

$$\tilde{G}^{(j)}(s_0) = G^{(j)}(s_0), \quad j = 0, 1, \dots, k-1.$$

That is, the first $k-1$ derivatives of G and $\tilde{G}$ coincide at s_0 . Considering the power series expansion (12) of the original and the reduced-order TFM, this is equivalent to saying that at least the first k moments $\tilde{M}_j(s_0)$ of the transfer function $\tilde{G}(s)$ of the ROM (3) are equal to the first k moments $M_j(s_0)$ of the TFM $G(s)$ of the original system (1) at the expansion point s_0 :

$$M_j(s_0) = \tilde{M}_j(s_0), \quad j = 0, 1, \dots, k-1.$$

If further the r columns of the unitary matrix W span the block Krylov subspace $\mathcal{K}_k(F, H)$ for $F = (A - s_0E)^{-T}E$ and $H = -(A - s_0E)^{-T}C^T$, applying the Petrov-Galerkin projection $\Pi = V(W^*V)^{-1}W^*$ to (1) yields a ROM whose TFM matches at least the first $2k$ moments of the TFM of the original system.

Theoretically, the matrix V (and W) can be computed by explicitly forming the columns which span the corresponding Krylov subspace $\mathcal{K}_k(F, H)$ and using the Gram-Schmidt algorithm to generate unitary basis vectors for $\mathcal{K}_k(F, H)$. The forming of the moments (the Krylov subspace blocks F^jH) is numerically precarious and has to be avoided under all circumstances. Using Krylov subspace methods to achieve an interpolation-based ROM as described above is recommended. The unitary basis of a (block) Krylov subspace can be computed by employing a (block) Arnoldi or (block) Lanczos method; see, e.g., Antoulas

(2005), Golub and Van Loan (2013), and Freund (2003).

In the case when an oblique projection is to be used, it is not necessary to compute two unitary bases as above. An alternative is then to use the nonsymmetric Lanczos process (Golub and Van Loan 2013). It computes bi-unitary (i.e., $W^*V = I_r$) bases for the abovementioned Krylov subspaces and the ROM as a by-product of the Lanczos process. An overview of the computational techniques for moment-matching and Padé approximation summarizing the work of a decade is given in Freund (2003) and the references therein.

In general, the discussed MOR approaches are instances of rational interpolation. When the expansion point is chosen to be $s_0 = \infty$, the moments are called Markov parameters, and the approximation problem is known as partial realization. If $s_0 = 0$, the approximation problem is known as Padé approximation.

As the use of one single expansion point s_0 leads to good approximation only close to s_0 , it might be desirable to use more than one expansion point. This leads to multipoint moment-matching methods, also called rational Krylov methods; see, e.g., Ruhe and Skoogh (1998), Antoulas (2005), and Freund (2003).

In contrast to balanced truncation, these (rational) interpolation methods do not necessarily preserve stability. Remedies have been suggested; see, e.g., Freund (2003).

The use of complex-valued expansion points will lead to a complex-valued ROM (3). In some applications (in particular, in case the original system is real valued), this is undesired. In that case one can always use complex-conjugate pairs of expansion points as then the entire computations can be done in real arithmetic.

The methods just described provide good approximation quality locally around the expansion points. They do not aim at a global approximation as measured by the $\mathcal{H}_2$ - or $\mathcal{H}_\infty$ -norms. In Gugercin et al. (2008), an iterative procedure is presented which determines locally optimal expansion points w.r.t. the $\mathcal{H}_2$ -norm approximation under the assumption that the order r of the ROM is prescribed and only 0th-

and 1st-order derivatives are matched. Also, for multi-input multi-output systems (i.e., m and p in (1) are both larger than one), no full moment matching is achieved but only tangential interpolation, $G(s_j)b_j = \tilde{G}(s_j)b_j$, $c_j^*G(s_j) = c_j^*\tilde{G}(s_j)$, $c_j^*G'(s_j)b_j = c_j^*\tilde{G}'(s_j)b_j$, for certain vectors b_j, c_j determined together with the optimal s_j by the iterative procedure.

Tools

Almost all commercial software packages for structural dynamics include modal analysis/truncation as a means to compute a ROM. Modal truncation and balanced truncation are available in the MATLAB® Control System Toolbox and the MATLAB® Robust Control Toolbox.

Numerically reliable, well-tested, and efficient implementations of many variants of balancing-based MOR methods as well as Hankel norm approximation and singular perturbation approximation can be found in the Subroutine Library In Control Theory (SLICOT, <http://www.slicot.org>) (Varga 2001). Easy-to-use MATLAB interfaces to the Fortran 77 subroutines from SLICOT are available in the SLICOT Model and Controller Reduction Toolbox (<http://slicot.org/matlab-toolboxes/basic-control>); see Benner et al. (2010). An implementation of moment-matching via the (block) Arnoldi method is available in MOR for ANSYS® (<http://modelreduction.com/Software.html>).

The MORLAB toolbox (<https://www.mpi-magdeburg.mpg.de/projects/morlab>) is a collection of MATLAB routines for different truncation-based MOR methods for LTI systems as well as for DAE and second-order systems.

The MOR Wiki (<https://morwiki.mpi-magdeburg.mpg.de/morwiki/>) is a platform for MOR research and provides discussions of a number of methods, as well as links to further software packages (e.g., MOREMBS, MORPACK, and pyMOR). Moreover, one can find an extensive set of benchmark examples of LTI systems from various applications given in

computer-readable format which can easily be used to test new algorithms and software.

Summary and Future Directions

MOR of LTI systems can now be considered as an established computational technique. Some open issues still remain and are currently investigated. These include methods yielding good approximation in finite frequency or time intervals. Though numerous approaches for these tasks exist, methods with sharp local error bounds are still under investigation. A related problem is the reduction of closed-loop systems and controller reduction. The generalization of the methods discussed in this essay to second-order systems of the form

$$\begin{aligned} M\ddot{x}(t) + D\dot{x}(t) + Kx(t) &= Fu(t), y(t) \\ &= C_px(t) + C_v\dot{x}(t) \end{aligned}$$

with $M, K, D \in \mathbb{R}^{s \times s}$, $F \in \mathbb{R}^{s \times m}$, $C_p, C_v \in \mathbb{R}^{q \times s}$ has only been partially achieved. Of course, linearization to an equivalent first-order system is always possible. But, in general, the ROM in first-order form cannot be transformed into a ROM in second-order form. An important problem class getting a lot of current attention consists of (uncertain) parametric systems, that is, systems of the form

$$\begin{aligned} E(p)\dot{x}(t; p) &= A(p)x(t, p) + B(p)u(t), y(t, p) \\ &= C(p)x(t, p) \end{aligned}$$

where all system matrices (and hence the state and the output) depend on d parameters $p \in \mathbb{R}^d$. While the system is linear in the state, all system matrices may depend nonlinearly on the parameters. Here it is important to preserve parameters as symbolic quantities in the ROM. Most of the current approaches are based in one way or another on interpolation; a recent survey can be found in Benner et al. (2015). MOR for nonlinear systems has also been a research topic for decades. Here often, sampling-based methods such as proper orthogonal decomposition or, in case of parameter-dependent problems, reduced

basis methods are employed. Tutorial-style introductions with references to further reading can be found in Benner et al. (2017). Still, the development of satisfactory methods in the context of control design having computable error bounds and preserving interesting system properties remains a challenging task.

Model Predictive Control for Power Networks

Ian A. Hiskens¹ and Maria Vrakopoulou²

¹University of Michigan, Ann Arbor, MI, USA

²Electrical and Electronic Engineering, University of Melbourne, Melbourne, VIC, Australia

Abstract

Large-scale power systems rely on a hierarchical control structure to operate reliably through a wide variety of disturbances.

As operating strategies adapt to incorporate emerging technologies and distributed resources such as renewable generation and storage, model predictive control (MPC) offers a systematic approach to coordinating diverse controls and providing decision support. MPC uses an approximate system model to determine an optimal control sequence over a finite horizon. The first instance of that control sequence is implemented on the system, the resulting system response is measured, and the process repeats. Power system applications of MPC include prevention of voltage instability, corrective control, and secondary frequency control.

Keywords

Model predictive control · Power system control · Power system dynamics

Introduction

Electrical power systems are large-scale, geographically spread systems that are continually responding to a wide variety of disturbances. Reliable operation of such systems depends upon a hierarchical control structure, from very fast fault protection action to system-wide control centers where operators continually monitor behavior and enact control decisions.

As new technologies emerge and greater investment is directed toward distributed renewable energy and storage assets, traditional operating strategies must adapt accordingly. Faced with a large number of distributed devices, system operators will find it ever more challenging to quickly identify the most useful control actions during system events. Model predictive control (MPC) offers a systematic approach to coordinating a variety of control devices while operating quickly and reliably. Hence, as systems operate closer and closer to their limits, the feedback control actions and decision support provided by MPC will play an invaluable role in responding to stressed network conditions.

Overview of Power System Control

Power systems are affected by disturbances that range from lightning-induced faults on transmission lines to fluctuations in renewable power generation. In the former case, protection associated with the vulnerable components operates almost instantly to prevent, or at least minimize, damage (Blackburn 1998). Because of the requirement for high response speed, decision-making is minimal. Such myopic behavior may, however, weaken the network, further exacerbating the disturbance and potentially initiating an uncontrollable cascade of outages. The blackout of the USA and Canada in August 2003 provides such an example (U.S.-Canada Power System Outage Task Force 2004).

At a slower time-scale, feedback control loops are employed to regulate transmission and distribution voltages, generator active power production, and system frequency (Kundur 1994). Voltage regulation is achieved through application of automatic voltage regulators (AVRs) on generators, tap-changing transformers, and a growing list of power-electronic devices. Governors are used to regulate generator active power. Both AVRs and governors are local feedback control loops, i.e., they measure and respond only to local conditions. In contrast, system frequency regulation is achieved through automatic generator control (AGC), also known as load frequency control (LFC), which is a feedback control strategy that adjusts generators that are widespread across the power system (Jaleeli et al. 1992).

System operators continually monitor power system behavior and enact higher-level control decisions. For example, in response to a transmission line being overloaded, i.e., the current on the line exceeding its allowable maximum, operators may redispatch generation and/or curtail load. However, they might decide to allow the line to remain temporarily overloaded based on forecast changes in renewable generation that will soon relieve the overload. Operator decision-making is becoming more complicated, though, with increasing reliance on distributed generation and storage, and newer technologies such as

dynamic line rating (Douglass and Edris 1996) and highly responsive load control (Callaway and Hiskens 2011). MPC offers a systematic framework for real-time feedback control and/or decision support for power systems that are operating under stressed conditions.

Model Predictive Control (MPC)

MPC uses an internal (approximate) model of the system to predict behavior and establish an optimal control sequence (Rawlings 2000). The control actions from the first step of this sequence are implemented on the actual system. Subsequent measurement of the resulting system behavior provides the initial conditions for MPC to again predict behavior and recalculate an optimal control sequence. The feedback inherent in the repetition of this process allows MPC to control a broad range of devices while effectively satisfying a multi-period constrained optimal power flow problem.

The control actions available to MPC depend upon the application, with further discussion in section “Applications.” In general, though, MPC has the potential to redispatch generation and storage; exercise demand response; adjust set-points for voltage regulating devices such as generators, tap-changing transformers, and Statcoms/SVCs; and adjust angle set-points for phase-shifting transformers.

Figure 1 outlines the MPC control strategy. At time k , all measurements z_k^{meas} necessary to

model the system are provided to the controller. These measurements include network configuration, voltage magnitudes, active/reactive power of generators and loads, active/reactive power flows on lines, transformer tap positions, storage state-of-charge, and transmission line temperatures. This information is obtained via SCADA and synchrophasor measurement data monitoring and harmonized through state estimation (Abur and Gómez-Expósito 2004). The power system state estimation process uses nonlinear least-squares to minimize the weighted error between the measurements and the corresponding quantities of the network model. This yields the estimated network state which consists of voltage magnitudes and angles at all nodes across the network. The initial conditions for the MPC system model $x[0|k]$ are derived from the voltage state of the network model, together with other measurements as required for particular applications.

MPC then builds an optimization problem to determine a control sequence $u[0 \dots M-1|k]$ over a horizon of M time-steps while considering its effects on states $x[1 \dots M|k]$. The control sequence is computed to track scheduled/forecast set-point values for both controlled quantities $u^{sp}[k \dots k+M-1]$, such as conventional and renewable generation and controllable demand, and states $x^{sp}[k+1 \dots k+M]$ over the prediction horizon. Forecasts for other exogenous quantities may also be required for certain applications. For example, weather forecasts across the geographical expanse of a power system are important when transmission line ratings are dependent

Model Predictive Control for Power Networks,

Fig. 1 Overview of MPC strategy, from Martin and Hiskens (2017)

upon the thermal characteristics of line conductors, or when load control actions include thermostatically controlled loads (TCLs).

Once an optimal control sequence has been computed, the controls from the first step of that sequence $u[0|k]$ are applied to the physical system. The physical system responds to the controls as time advances from k to $k + 1$, and the process repeats when new system measurements z_{k+1}^{meas} become available.

Power system behavior is inherently nonlinear, with implications for MPC modelling and computational complexity. Care must be taken to develop approximate models that are sufficiently accurate to capture the phenomena of interest, yet still give tractable MPC optimization formulations that provide convergence and performance guarantees (Molzahn and Molzahn 2019). Linear models are most appealing, of course, with the “DC power flow” model forming the basis for various MPC formulations. This simplification of the power flow provides reasonable accuracy for active power flow over transmission lines but does not capture reactive power flows nor voltage magnitudes. Resulting MPC formulations are therefore blind to abnormal bus voltages and situations where high reactive power flow contributes to line overloading.

Other MPC strategies use the Jacobian which is obtained by linearizing the nonlinear power flow equations about the current operating point. The justification is that MPC introduces relatively small changes; therefore, the linearized model is sufficient to describe the resulting behavior. Typically the linearization is repeated at each MPC cycle. MPC formulations have also made use of trajectory sensitivities, which describe (to first order) the change in a trajectory due to perturbations in initial conditions. In this case, the nominal trajectory is computed using a nonlinear system model, with trajectory sensitivities (approximately) describing perturbations in the trajectory due to changes in the control variables.

Incorporating large-scale power systems into multi-period optimization gives high-dimensional problems that may incur unacceptably long solution times and exhibit numerical

instability. However, power system disturbances, such as line outages, tend to impact localized regions of power systems and require regional control actions. Therefore, while it is important for the entire system to be monitored for disturbances, there is no need for MPC to always model the system in its entirety. Rather, MPC should adaptively determine and model the disturbed subsystem, with the composition of that subsystem chosen to ensure that the impact of the disturbance and the potential control actions are adequately captured. An approach based on line-flow sensitivities is presented in Martin and Hiskens (2017).

Applications

The first application of MPC to emergency control of power systems was (Larsson et al. 2002), where voltage stability was achieved through optimal coordination of load shedding, capacitor switching, and tap-changer operation. A tree-based search method was employed to obtain optimal control actions from discrete switching events. Later MPC strategies for alleviating voltage instability employed nonlinear power system models and used trajectory sensitivities to approximate the impact of control actions on system behavior (Zima and Andersson 2005; Hiskens and Gong 2005; Jin et al. 2008).

Early investigations into the use of MPC for relieving thermal overloading of transmission lines were undertaken in Otomega et al. (2007). To return line currents to within their long-term ratings following a contingency, MPC regulated the angle on phase-shifting transformers, redispatched generation, and shed load as a last resort. The study found that both the length of the prediction horizon and the accuracy of the network model can have an appreciable influence on the ability of MPC to meet its control objectives. The work presented in Carneiro and Ferrarini (2010) further expanded on those ideas by incorporating a temperature-based model of transmission lines. Enforcing a temperature limit on a transmission line

while considering actual ambient conditions provides greater flexibility than the conservative assumptions typically used in device ratings. The shift toward distributed renewable generation and energy storage technologies has motivated further investigation of MPC-based cascade mitigation. In Martin and Hiskens (2017); Almassalkhi and Hiskens (2015), brief temperature overloads are relieved using energy storage and curtailment of renewables in addition to the control measures utilized in Otomega et al. (2007); Carneiro and Ferrarini (2010). An approach to extending control to large networks was developed and demonstrated in Martin and Hiskens (2017) using a 4259-bus model of the Californian electricity network.

MPC has also been explored for automatic generation control (AGC). AGC is used in most interconnected power systems to restore system frequency to its set-point value and regulate tie-line interchange (Jaleeli et al. 1992). These objectives are achieved by adjusting the active power set-points of generators throughout the system, taking into account restrictions on the amount and rate of generator power deviations. To cope with the expansive nature of power systems, a distributed control structure has been adopted for AGC. The current form of AGC may not, however, be well suited to future power systems where greater utilization of intermittent renewable resources brings with it power flow fluctuations that are difficult to regulate. Distributed MPC offers an effective means of achieving the desired controller coordination and performance improvements while alleviating the organizational and computational burden associated with centralized control (Venkat et al. 2008).

Summary and Future Directions

MPC offers a systematic approach to coordinating diverse power system resources and providing decision support. Power system applications of MPC range from prevention of voltage collapse and cascading failures in large-scale

power systems to optimally regulating energy storage in local energy hubs. As power systems grow in complexity, the predictive capability of MPC will become increasingly important for ensuring appropriate response following large disturbances. Furthermore, the structural characteristics of power systems suggest a greater role for distributed forms of MPC.

Abstract

Model predictive control (MPC) refers to a class of computer control algorithms that utilize an explicit mathematical model to optimize the predicted behavior of a process. At each control interval, an MPC algorithm computes a sequence of future process adjustments that optimize a specified control objective. The first adjustment is implemented and then the calculation is repeated at the next control cycle. Originally developed to meet the particular needs of petroleum refinery and power plant control problems, MPC technology has evolved significantly in both capability and scope and can now be found in many other control application domains.

Keywords

Predictive control · Computer control · Mathematical programming

Introduction

Model predictive control (MPC) refers to a class of computer control algorithms that utilize an explicit mathematical model to predict future process behavior. At each control interval, in the most general case, an MPC algorithm solves a sequence of nonlinear programs to answer three essential questions: where is the process heading (prediction), where should the process go (steady-state target optimization), and what is the best sequence of adjustments to send it to the right place (dynamic optimization)? The first adjustment is then implemented, and then the

entire calculation sequence is repeated at the subsequent control cycles.

MPC technology arose first in the context of petroleum refinery and power plant control problems for which the well-known linear quadratic Gaussian (LQG) methods were found to be inadequate (Richalet et al. 1978; Cutler and Ramaker 1979). Specific needs that drove the development of MPC technology include the need for economic optimization and strict enforcement of safety and equipment constraints. Promising early results led to a wave of successful industrial applications, sparking the development of several commercial offerings (Qin and Badgwell 2003) and generating intense interest from the academic community (Mayne et al. 2000). Today MPC technology permeates the refining and chemical industries and has gained increasing acceptance in a wide variety of areas including chemicals, automotive, aerospace, and food processing applications. The total number of MPC applications in the petrochemical industry was estimated in 2010 to be 5,000–10,000 with total benefits of 1–2 billion \$/year (Badgwell 2010).

This entry focuses on how MPC is implemented in refining and chemical plant applications. A more detailed summary of the history of MPC technology development, as well as a survey of commercial offerings through 2003, can be found in the review article by Qin and Badgwell (2003). Darby and Nikolaou present a more recent summary of MPC practice (Darby and Nikolaou 2012). Textbook descriptions of MPC theory and design, suitable for classroom

use, include Maciejowski (2002) and Rawlings et al. (2017).

MPC Fired Heater Example

An example from petroleum refining will be used to introduce basic nomenclature and concepts and illustrates many of the issues that arise in the practice of MPC. Consider the simplified fired heater in Fig. 1. A feed stream of cold oil splits into two tubes that pass over burners fired by fuel gas. The tubes then recombine to produce a heated oil stream that continues on for further processing. The circles indicate measurements and flow controllers most relevant to heater operation. These fall into three basic groups. The green group, known as manipulated variables (MVs), correspond to variables that the MPC algorithm (or a human operator) may adjust to achieve the desired control objectives. These are the setpoint of the tube 1 flow controller FC1, the setpoint of the tube 2 flow controller FC2, and the setpoint of the fuel gas flow controller FG. The red group, known as disturbance variables (DVs), are measurements that provide feedforward information for the control algorithm. Here the DVs are the two tube oil inlet temperatures TI1 and TI2. The blue group, known as controlled variables (CVs), are measurements of the quantities that must be controlled. This includes the external skin temperature of each tube TS1 and TS2, the oil outlet temperature for each tube TO1 and TO2, and the combined oil outlet temperature TO and fuel gas outlet temperature FO.

Model Predictive Control in Practice,

and TO2, and the combined oil temperature TO and flow rate FO exiting the heater.

The fired heater MPC design specification is presented in Table 1, which lists the key process variables and corresponding specifications. A vital aspect of the MPC design is the requirement to prioritize the CVs. This is done to make sure that the control focuses first on the most important goals and then tries to achieve remaining goals in a prioritized order only if enough degrees of freedom are available. The highest priority specifications involve constraints associated with safety. Lower-level priorities typically include meeting desired product specifications and saving energy. For the fired heater example, the top priority is to make sure that tube skin temperatures TS1 and TS2 do not exceed a maximum safety limit. The second and third priorities are to achieve the desired combined

oil outlet temperature and flow rate. A fourth priority, when conditions allow, is to balance the tube outlet temperatures TO1 and TO2 in order to maximize heat transfer efficiency. For this purpose we define a delta temperature variable DT as the difference between the tube 1 and 2 oil outlet temperatures. Note that maximum, minimum, and rate of change limits are provided for each MV. These do not have an associated priority because they can always be enforced.

After laying out the MPC design specification, the next step is to develop a mathematical model that predicts the effects of MV and DV changes on the CVs. Figure 2 illustrates how the model can be viewed in terms of process inputs (MVs and DVs) and process outputs (CVs). Such a model is often referred to as multiple-input/multiple-output (MIMO). The vast majority of industrial MPC applications rely

on a linear empirical MIMO model developed from process step response data.

Figure 3 illustrates a process step test for the fired heater. The process inputs are plotted in the left column, and the process outputs are shown in the right column. Time in minutes is plotted on the horizontal axis. At the 10 min mark, we increase the fuel gas flow FG from 95 to 97 SCFH and then return it to 95 SCFH 10 min later. In the right column, the effects of this pulse on the CVs can be seen. The combined oil outlet temperature TO increases by a little more than 10 F and then comes back down again. The combined oil flow rate FO and the tube outlet temperature difference DT remain unchanged, while both tube skin temperatures TS1 and TS2 rise and then fall. With this information we can derive all of the models related to fuel gas flow FG. In a similar way, we make changes to the two tube flow controllers FC1 and FC2 and observe the responses of the CVs. Since we cannot directly change the tube inlet temperature DVs, we must either search historical data, or, as shown here, we assume that we are able to make changes to upstream equipment to increase the oil inlet temperature. In the ideal case shown here, we are able to make significant, independent changes to each process input, and we collect significant, essentially noise-free data that shows the effects on each output.

The step test data are then passed into appropriate modeling software to develop a dynamic model. The data must first be edited to remove effects that we do not want to include in the model, such as might happen during a process upset. The data are then typically band-pass filtered to remove the steady-state information and any high-frequency noise. A subspace identification method (Ljung 1999) can then be used to identify a linear state-space model. The step response of the resulting model is illustrated in Fig. 4. In this representation, the process inputs appear as columns, and the process outputs appear as rows. Each column shows how the outputs would respond to a pure unit step change increase in the given input. For example, the middle column shows how the CVs respond to a unit increase in the fuel

gas flow rate FG. The final value in each cell is known as the process gain. The first cell in the middle column shows that the combined outlet temperature TO increases by about 6 F, so the gain for this model is 6 DEGF/SCFH. The second and third cells show no changes for the combined outlet flow FO and the tub outlet delta temperature DT. The last two cells show that the tube skin temperatures both increase by about 10 F. Of course these responses match the data that was recorded during the step test.

Figure 5 shows how the fired heater MPC application is configured. The application runs at a 1-minute frequency in a dedicated PC, communicating with the process instrumentation through a standard protocol such as *OPC*. Every minute it reads in current values of the CVs and DVs and then sends an adjustment out to the MVs.

Results from a closed-loop test of the fired heater MPC are shown in Fig. 6. Again the process inputs are shown in the left column, and process outputs appear in the right column. The first change occurs at the 10-minute mark, when the operator increases the TO setpoint by 5 F. The control responds by sharply increasing FG from 95 to over 97 SCFH and then bringing it down to settle around 96 SCFH. This has the effect of increasing TO quickly up to the new setpoint of 755 F. There is, of course, no change in FO or DT, but TS1 and TS2 both increase as expected.

The next change comes at the 30 min mark when the operator asks to increase FO by 20 BPH without changing TO or DT. The MPC accomplishes this by increasing both FC1 and FC2 while also carefully increasing FG in such a way that TO remains constant.

Having successfully added 20 BPH of feed, the operator tries to do the same thing at the 50 min mark. This time, however, the MPC determines right away that it will not be able to reach the new setpoint of 240 BPH. The steady-state target for FO (green line) only goes up to around 235 BPH. MPC stops short on the FO because it predicts that it will run out of room on the tube skin temperatures TS1 and TS2. We have configured these limits as the top priority control specifications, so the MPC will not allow these limits to be violated. This places a limit on the

Model Predictive Control in Practice, Fig. 3 Fired heater step test

Model Predictive Control in Practice, Fig. 4 Fired heater step response model

Model Predictive Control in Practice, Fig. 5 Fired heater MPC configuration

available heat input, and we have said that the next highest priority is to maintain the heater outlet temperature TO, so the control gives up on the FO setpoint. This illustrates how priorities are used to resolve conflicting control objectives in a MPC application.

At the 70 min mark, we can see that the oil entering the first tube begins to warm up. This means that less energy will be required to meet the TO setpoint so the control is able to push a little more feed into the heater. It increases FC1 and FC2 in order to keep DT as close to zero as possible. At 85 min the other tube inlet temperature increases enough to allow the FO setpoint to be reached.

MPC Control Hierarchy

In a modern chemical plant or refinery, the MPC controller is part of a multilevel hierarchy, as illustrated in Fig. 7. Moving from the top level to the bottom, the control functions execute at a higher frequency but cover a smaller geographic scope. At bottom level, referred to as Level 0, basic proportional-integral-derivative (PID) controllers execute once a second within distributed control system (DCS) hardware. These controllers adjust individual valves to

maintain desired flows (FC), pressures (PC), levels (LC), and temperatures (TC).

At Level 1 a MPC controller runs once a minute to perform dynamic constraint control for an individual processing unit, such as crude distillation unit or a fluid catalytic cracker (Gary et al. 2007). It has the job of holding the unit at the best economic operating point in the face of dynamic disturbances and operational constraints.

At Level 2 a real-time optimizer (RTO) runs hourly to calculate optimal steady-state targets for a collection of processing units. It uses a rigorous first-principles steady-state model to calculate targets for key operating variables such as unit temperatures and feed rates. These are typically passed down to several MPC controllers for implementation.

At Level 3 planning and scheduling functions are carried out daily to optimize economics for an entire chemical plant or refinery. Key operating targets and economic data are typically passed to several RTO applications for implementation.

MPC Algorithms

MPC algorithms function in much the same way that an experienced human operator would approach a control problem. Figure 8 illustrates the flow of information for a typical MPC

Model Predictive Control in Practice, Fig. 6 Fired heater MPC closed-loop test (U – process input, U_s – input steady-state target (computed by MPC), U_t – input target (entered by operator), $U_{\max}$ – input maximum limit, $U_{\min}$ – input minimum limit, Y – process output, Y_s – output steady-state target (computed by MPC), Y_t – output target (entered by operator), $Y_{\max}$ – output maximum limit, $Y_{\min}$ – output minimum limit)

Model Predictive Control in Practice, Fig. 7 Hierarchy of control functions in a refinery/chemical plant

Model Predictive Control in Practice, Fig. 8 Information flow for MPC algorithm

implementation. At each control interval, the algorithm compares the current model output prediction to the measured output and passes this information to a state estimator. The state estimate, which includes an estimate of the process disturbances, is then passed to a steady-state optimization to determine the best operating point for the unit. The steady-state state and input targets are then passed, along with the state estimate, to a dynamic optimization to compute the best trajectory of future MV adjustments. This trajectory of future MV adjustments is often referred to as a move plan. The first computed MV adjustment is then implemented, and the entire calculation sequence is repeated at the next

control interval. The various commercial MPC algorithms differ in such details as the mathematical form of the dynamic model and the specific formulations of the state estimation, steady-state optimization, and dynamic optimization problems (Qin and Badgwell 2003). A general formulation that illustrates the most important concepts is presented in the subsections below.

Model Types

A state-space model used in MPC can be written in the following form:

$$\begin{aligned}
x_{k+1} &= f(x_k, u_k) + w_k && \text{state dynamics} \\
y_k &= g(x_k, u_k) + v_k && \text{output response} \\
u &\in R^m && \text{inputs (MVs and DVs)} \\
y &\in R^l && \text{outputs (CVs)} \\
x &\in R^n && \text{states} \\
w &\sim N(0, Q_e) && \text{state disturbance} \\
v &\sim N(0, R_e) && \text{measurement noise}
\end{aligned}$$

This is a discrete model form in which k indexes the control intervals. The state transition function $f(x_k, u_k)$ and the measurement function $g(x_k, u_k)$ are typically developed through some combination of first-principles knowledge and step test data.

State Estimation

The state estimation problem can be posed as an optimization over a window of past process behavior, defined by past inputs u_k and past measured outputs $\hat{y}_k$:

$$\begin{aligned}
\min_{x_{k-N_e} \cdots x_k} \quad & \Phi = P_{k-N_e}(x_{k-N_e}) \\
& + \sum_{j=k-N_e}^{k-1} \left(w_j^T Q_e^{-1} w_j \right) \\
& + \sum_{j=k-N_e}^k \left(v_j^T R_e^{-1} v_j \right) \\
s.t. : \quad & x_{j+1} = f(x_j, u_j) + w_j; \\
& \hat{y}_j = g(x_j, u_j) + v_j; x_j \in X
\end{aligned}$$

This formulation, known as moving horizon estimation (MHE), is solved at each sample time and provides a very flexible way to enforce realistic constraints on the estimated state. The goal is to estimate the sequence of states that best optimizes the trade-off between process disturbances and measurement noise.

Steady-State Optimization

The steady-state optimization problem can be written as follows:

$$\begin{aligned}
\min_{x_s, u_s} \quad & \Phi = (y_t - y_s)^T Q_c (y_t - y_s) \\
& + (u_t - u_s)^T R_c (u_t - u_s) \\
s.t. : \quad & x_s = f(x_s, u_s); \\
& y_s = g(x_s, u_s); x_s \in X; u_s \in U
\end{aligned}$$

where u_t and y_t are desirable targets from upper-level optimization results. Here the goal is to drive the steady-state target as close as possible to these targets.

Dynamic Optimization

The dynamic optimization problem can be posed as an optimization over future process behavior:

$$\begin{aligned}
\min_{u_k \cdots u_{k+N_c-1}} \quad & \Phi \\
& = \sum_{j=0}^{N_c-1} \left[(y_s - y_{k+j})^T Q_c (y_s - y_{k+j}) \right. \\
& \quad + (u_s - u_{k+j})^T R_c (u_s - u_{k+j}) \\
& \quad \left. + \Delta u_{k+j}^T S_c \Delta u_{k+j} \right] + P_{k+N_c}(z_{k+N_c}) \\
s.t. : \quad & z_{j+1} = f(z_j, u_j); \\
& y_j = g(z_j, u_j); \\
& z_0 = x_k; z_j \in X; u_j \in U
\end{aligned}$$

An optimal sequence of future input adjustments is computed by trading off between three competing goals: driving the outputs to their steady-state targets, driving the inputs to their steady-state targets, and minimizing input movement.

Numerical Solution Methods

In the general case, the MPC algorithm must solve the three optimization problems outlined above at each control interval. For the case of linear models and reasonable tuning parameters, these problems take the form of a convex quadratic program (QP) with a constant, positive definite Hessian. As such they can be solved relatively easily using standard optimization codes. For the case of a linear state-space model, the structure can be exploited even further to develop a specialized solution algorithm using an interior point method (Rao et al. 1998).

For the case of nonlinear models, these problems take the form of a nonlinear program for which the solution domain is no longer convex. This greatly complicates the numerical solution. A typical strategy is to iterate on a linearized

version of the problem until convergence (Bielger 2010).

MPC Implementation

The combined experience of thousands of MPC applications in the process industries has led to a near consensus on the steps required for a successful implementation. These are justification, pretest, step test, modeling, control configuration, commissioning, postaudit, and sustainment. These steps must be carried out by a carefully selected project team that typically includes, in addition to the MPC expert, an engineer with detailed knowledge of the process and an operator with considerable operations experience. The following subsections describe these steps for a typical implementation of MPC with a linear model on a refinery or chemical process unit.

Justification

Application of MPC technology in industry can only be justified by the resulting economic benefits. Therefore the first step in an MPC application is to estimate the potential economic benefits and associated project costs. MPC technology makes money primarily by minimizing variations in key variables and then moving the operation closer to constraints. Consider the example of controlling the amount of impurity in a product, illustrated in Fig. 9. Under operator control the variation in the impurity level may be quite large, so that the average operating point must be moved far below the maximum specification limit in order to prevent limit violations. With a good multivariable control, the variation is reduced significantly, but there is no benefit until the average amount of impurity in the product is increased. This is what happens under MPC control. The average amount of impurity in the product increases significantly without violating the maximum specification limit. This in turn allows more profitable operation, either by allowing more feed to be pushed through the unit or by lowering the operating cost.

Project expenditures include engineering expenses, hardware and software costs, additional manpower required for step tests and commissioning, lost-opportunity costs associated with step testing, and charges for operator training, postaudit, and sustainment.

In addition to increased throughput and/or lower operating costs, there are often less tangible benefits that result from an application of MPC technology. These include such things as fixing broken instruments and valves, de-bottlenecking the limiting constraints, and increased reliability from more consistent operation. Representative estimates of the net benefits are typically in the range of \$100,000 to \$1,000,000 per year, with payback times for the entire project in the range of 3 months to 1 year.

Pretest

The goal of the pretest is to evaluate overall unit operation and reach a consensus on a preliminary control design. This includes testing each of the MVs to see if there are tuning or valve problems and monitoring the quality and timing of the CV measurements. It is quite common to find MV controllers (flow, temperature, pressure, and level) that must be returned or valves that must be replaced prior to control commissioning. CV measurements may be too noisy or may be available only intermittently. Disturbances to the unit must be identified along with corresponding feedforward measurements (DV's), if any. Control hardware or software issues must be identified so that they can be addressed prior to control commissioning. Control design discussions must include prioritization of the CV specifications. As in the fired-heater example discussed earlier, the CVs can typically be grouped into three categories: safety limits, product specifications, and economic optimization.

Step Test

The goal of the step test is to produce a high-quality data set for use in model development. In the best case, these data will include the full range of typical operation and will show clearly how adjustments in each of the MVs and DVs affect each of the CVs. The tests must be conducted

munication between the MPC control computer and the process hardware. Initially conservative tuning is then entered, and the MPC components are tested using a combination of process data and closed-loop simulation. For the simulations, the model is typically assumed to be perfect, and each of the key process specifications is activated by changing limits. The timing and magnitude of the resulting MV and CV responses can then be adjusted changing the tuning factors.

Commissioning

The goal of commissioning is to verify correct control behavior for the most important control scenarios and to finalize control tuning for long-term operation. The state estimator is turned on first to verify reasonable behavior for the CV predictions. Estimator tuning may be adjusted manually or calculated from process operating data (Odelson et al. 2006). MV connections are then verified, one at a time, by activating the MVs and adjusting the limits in a region very close to current operation. MV limits are then widened incrementally while testing each of the key CV specifications. CV response testing usually leads to significant changes in control tuning.

The duration of commissioning is dictated by the closed-loop response time of CVs. Typically several tests of each CV specification are required to verify correct closed-loop behavior. Operator training is often conducted during this period.

Postaudit

After operating for a significant amount of time, typically several months, a postaudit is conducted to verify estimated benefits and to catalogue areas for improving the MPC controller. This activity usually results in a ranked list of additional CVs to be included in the controller.

Sustainment

Inevitable process and disturbance changes necessitate an aggressive program of daily analysis and maintenance to sustain the economic benefits of an MPC controller. This often includes analysis of carefully defined metrics for the overall controller and for each MV and CV. Maintenance activities include controller

returning, model adjustments, and addition of new MVs and CVs.

Summary and Future Directions

Model predictive control is now a mature technology in the process industries. A representative MPC algorithm in this domain includes a state estimator, a steady-state optimization, and a dynamic optimization, running once a minute. A successful MPC application usually starts with a careful economic justification, includes significant participation from process engineers and operators, and is maintained with an aggressive sustainment program. Many thousands of such applications are currently operating around the world, generating billions of dollars per year in economic benefits.

Likely future directions for MPC practice include increasing use of nonlinear models, improved state estimation through unmeasured disturbance modeling (Pannocchia and Rawlings 2003), and development of more efficient numerical solution methods (Zavala and Biegler 2009).

Model Reference Adaptive Control

Jing Sun

University of Michigan, Ann Arbor, MI, USA

Abstract

The fundamentals and design principles of model reference adaptive control (MRAC) are described. The controller structure and adaptive algorithms are delineated. Stability and convergence properties are summarized.

Keywords

Certainty equivalence · Lyapunov-SPR design · MIT rule

MRAC

Introduction

Model reference adaptive control (MRAC) is an important adaptive control approach, supported by rigorous mathematical analysis and effective design toolsets. It is made up of a feedback control law that contains a controller $C(s, \theta_c)$ and an adjustment mechanism that generates the controller parameter updates $\theta_c(t)$ online. While different MRAC configurations can be found in the literature, the structure shown in Fig. 1 is commonly used and includes all the basic components of an MRAC system. The prominent features of MRAC are that it incorporates a reference model which represents the desired input–output behavior and that the controller and adaptation law are designed to force the response of the plant, y_p , to track that of the reference model, y_m , for any given reference input r .

Different approaches have been used to design MRAC, and each may lead to a different implementation scheme. The implementation schemes fall into two categories: direct and indirect MRAC. The former updates the controller parameters θ_c directly using an adaptive law, while the latter updates the plant parameters θ_p first using an estimation algorithm and then updates θ_c by solving, at each time t , certain algebraic equations that relate θ_c with the online estimates of θ_p . In both direct and indirect MRAC schemes, the controller structure is kept the same

Model Reference Adaptive Control, Fig. 1 Schematic of MRAC

as that which would be used in the case that the plant parameters are known.

MRC Controller Structure

Consider the design objective of model reference control (MRC) for linear time-invariant systems: Given a reference model $M(s)$, find a control law such that the closed-loop system is stable and $y_p \rightarrow y_m$ as $t \rightarrow \infty$ for any bounded reference signal r .

For the case of known plant parameters, the MRC objective can be achieved by designing the controller so that the closed-loop system has a transfer function equal to $M(s)$. This is the so-called model matching condition. To assure the existence of a causal controller that meets the model matching condition and guarantees internal stability of the closed-loop system, the following assumptions are essential:

- A1. The plant has a stable inverse, and the reference model is chosen to be stable.
- A2. The relative degree of $M(s)$ is equal to or greater than that of the plant $G_p(s)$. Herein, the relative degree of a transfer function refers to the difference between the orders of the denominator and numerator polynomials.

It should be noted that these assumptions are imposed to the MRC problem so that there is enough structural flexibility in the plant and in the reference model to meet the control objectives. A1 is necessary for maintaining internal stability of the system while meeting the model matching condition, and A2 is needed to ensure the causality of the controller. Both assumptions are essential for non-adaptive applications when the plant parameters are known, let alone for the adaptive cases when the plant parameters are unknown.

The reference model plays an important role in MRAC, as it will define the feasibility of MRAC design as well as the performance of

the resulting closed-loop MRAC system. The reference model should reflect the desired closed-loop performance. Namely, any time-domain or frequency-domain specifications, such as time constant, damping ratio, natural frequency, bandwidth, etc., should be properly reflected in the chosen transfer function $M(s)$.

The controller structure for the MRAC is derived with these assumptions for the known plant case and extended to the adaptive case by combining it with a proper adaptive law. Under assumptions A1–A2, there exist infinitely many control solutions C that will achieve the MRC design objective for a given plant transfer function $G_p(s)$. Nonetheless, only those extendable to MRAC with the simplest structure are of interest. It is known that if a special controller structure with the following parametrization is imposed, then the solution to the model matching condition, in terms of the ideal parameter θ_c^* , will be unique:

$$u_p = \theta_1^{*T} \omega_1 + \theta_2^{*T} \omega_2 + \theta_3^{*T} y_p + c_0^* r = \theta_c^{*T} \omega$$

where $\theta_c^* \in R^{2n}$, n is the order of the plant,

$$\theta_c^* = \begin{bmatrix} \theta_1^* \\ \theta_2^* \\ \theta_3^* \\ c_0^* \end{bmatrix}, \omega = \begin{bmatrix} \omega_1 \\ \omega_2 \\ y_p \\ r \end{bmatrix}$$

and $\omega_1, \omega_2 \in R^{n-1}$ are signals internal to the controller generated by stable filters (Ioannou and Sun 1996).

This MRC control structure is particularly appealing for adaptive control development, as the parameters appear linearly in the control law expression, leading to a convenient linear parametric model for adaptive algorithm development.

Adaptation Algorithm

Design of adaptive algorithms for parameter updating can be pursued in several different approaches, thereby resulting in different MRAC schemes. Three direct design approaches,

namely, the Lyapunov-SPR, the certainty equivalence, and the MIT rule, will be briefly described together with indirect MRAC.

Lyapunov-SPR Design

One popular MRAC algorithm is derived using Lyapunov's direct method and the Meyer-Kalman-Yakubovich (MKY) Lemma based on the strictly positive real (SPR) argument. The concept of SPR transfer functions originates from network theory and is related to the driving point impedance of dissipative networks. The MKY Lemma states that given a stable transfer function $M(s)$ and its realization (A, B, C, d) where $d \geq 0$ and all eigenvalues of the matrix A are in the open left half plane: If $M(s)$ is SPR, then for any given positive definite matrix $L = L^T > 0$, there exists a scalar $\nu > 0$, a vector q , and a $P = P^T > 0$ such that

$$\begin{aligned} A^T P + P A &= -q q^T - \nu L \\ P B - C &= \pm q \sqrt{2d} \end{aligned}$$

By choosing $M(s)$ to be SPR, one can formulate a Lyapunov function consisting of the state tracking and parameter estimation errors and use the MKY Lemma to define the adaptive law that will force the derivative of the Lyapunov function to be semi-negative definite. The resulting adaptive law has the following simple form:

$$\dot{\theta} = -\Gamma e_1 \omega \text{sign}(c_0^*)$$

where $e_1 = y_p - y_m$ is simply the tracking error and $c_0^* = k_m/k_p$ with k_m, k_p being the high frequency gain of the transfer function for the reference model $M(s)$ and the plant $G_p(s)$, respectively. This algorithm, however, applies only to systems with relative degree equal to 0 or 1, which is implied by the SPR condition imposed on $M(s)$ and assumption A2.

The Lyapunov-SPR-based MRAC design is mathematically elegant in its stability analysis but is restricted to a special class of systems. While it can be extended to more general cases with relative degrees equal to 2 and 3, the resulting

control law and adaptive algorithm become much more complicated and cumbersome as efforts must be made to augment the control signal in such a way that the MKY Lemma is applicable to the "reformulated" reference model.

Certainty Equivalence Design

For more general cases with a high relative degree, another design approach based on "certainty equivalence" (CE) principle is preferred, due to the simplicity in its design as well as its robustness properties in the presence of modeling errors. This approach treats the design of the adaptive law as a parameter estimation problem, with the estimated parameters being the controller parameter vector θ_c^* . Using the specific linear formulation of the control law and assuming that θ_c^* satisfies the model matching condition, one can show that the ideal controller parameter satisfies the following parametric equation:

$$z = \theta_c^{*T} \omega_p$$

with

$$z = M(s)u_p, \omega_p = \begin{bmatrix} M(s)\omega_1 \\ M(s)\omega_2 \\ M(s)y_p \\ y_p \end{bmatrix}$$

This parametric model allows one to derive adaptive laws to estimate the unknown controller parameter θ_c^* using standard parameter identification techniques, such as the gradient and least squares algorithms. The corresponding MRAC is then implemented in the CE sense where the unknown parameters are replaced by their estimated value. It should be noted that a CE design does not guarantee closed-loop stability of the resulting adaptive system, and additional analysis has been carried out to establish closed-loop stability.

MIT Rule

Besides the Lyapunov-SPR and CE approaches mentioned earlier, the direct MRAC problem can

also be approached using the so-called MIT rule, an early form of MRAC developed in the 1950s–1960s in the Instrumentation Laboratory at MIT for flight control. The designer defines a cost function, e.g., a quadratic function of tracking error, and then adjusts parameters in the direction of steepest descent. The negative gradient of the cost function is usually calculated through the sensitivity derivative approach. The formulation is quite flexible, as different forms of MIT rule can be derived by changing the cost function following the same procedure and reusing the same sensitivity functions. Despite its effectiveness in some practical applications, MRAC systems designed with MIT rule have had stability and robustness issues.

Indirect MRAC

While most of the MRAC systems are designed as direct adaptive systems, indirect MRAC systems can also be developed which explicitly estimate the plant parameter θ_p as an intermediate step. The adaptive law for an indirect MRAC includes two basic components: one for estimating the plant parameters and another for calculating the controller parameters based on the estimated plant parameters. This approach would be preferred if the plant transfer function is partially known, in which case the identification of the remaining unknown parameters represents a less complex problem. For example, if the plant has no zeros, the indirect scheme estimates $n + 1$ parameters, while the direct scheme has to estimate $2n$ parameters.

Indirect MRAC is a CE-based design. As such, the design is intuitive but the design process does not guarantee closed-loop stability, and separate analysis has to be carried out to establish stability. Except for systems with a low number of zeros, the “feasibility” problem could also complicate the matter, in the sense that the MRC problem may not have a solution for the estimated plant at some time instants even though the solution exists for the real plant. This problem is unique to the indirect design, and several mitigating

solutions have been found at the expense of more complicated adaptation or control algorithms.

Stability, Robustness, and Parameter Convergence

Stability for MRAC often refers to the properties that all signals are bounded and tracking error converges to zero asymptotically. Robustness for adaptive systems implies that signal boundedness and tracking error convergence (to a small residue set) will be preserved in the presence of small perturbations such as disturbances, un-modeled dynamics, and time-varying parameters. For different MRAC schemes, different approaches are used to establish their properties.

For the Lyapunov-SPR-based MRAC systems, stability is established in the design process where the adaptive law is derived to enforce a Lyapunov stability condition. For CE-based designs, establishing stability for the closed-loop MRAC system is a nontrivial exercise for both direct and indirect schemes. Using properly normalized adaptive laws for parameter estimation, however, stability can be proved for direct and indirect MRAC schemes. For MRAC systems designed with the MIT rule, local stability can be established under more restrictive conditions, such as when the parameters are close to the ideal ones.

It should be noted that the adaptive control algorithm in the original form has been shown to have robustness issues, and extensive publications in the 1980s and 1990s were devoted to robust adaptive control in attempts to mitigate the problem. Many modifications have been proposed and shown to be effective in “robustifying” the MRAC; interested readers are referred to the article on ► [Robust Adaptive Control](#) for more details.

Parameter convergence is not an intrinsic requirement for MRAC, as tracking error convergence can be achieved without parameter convergence. It has been shown, however, that parameter convergence could enhance robustness, particularly for indirect schemes. As in the case for parameter identification, a persistent excitation (PE) condition needs to

be imposed on the regression signal to assure parameter convergence in MRAC. In general, PE is accomplished by properly choosing the reference input r . It can be established for most MRAC approaches that parameter convergence is achieved if, in addition to conditions required for stability, the reference input r is sufficiently rich of order $2n$, $\dot{r}$ is bounded, and there is no pole-zero cancelation in the plant transfer function. A signal is called to be sufficiently rich of order m if it contains at least $m/2$ distinct frequencies.

Summary and Future Directions

MRAC incorporates a reference model to capture the desired closed-loop responses and designs the control law and adaptation algorithm to force the output of the plant to follow the output of the reference model. Several different design approaches are available. Stability, robustness, and parameter convergence have been established for different MRAC designs with appropriate assumptions.

MRAC had been a very active and fruitful research topic from the 1960s to 1990s, and it formed important foundations for modern adaptive control theory. It also found many successful applications ranging from chemical process controls to automobile engine controls. More recent efforts have been mostly devoted to integrating it with other design approaches to treat nonstandard MRAC problems for nonlinear and complex dynamic systems.

Model-Based Performance Optimizing Control

Sebastian Engell

Fakultät Bio- und Chemieingenieurwesen,
Technische Universität Dortmund, Dortmund,
Germany

Abstract

In many applications, e.g., in chemical process control, the purpose of control is to achieve an optimal performance of the controlled system despite the presence of significant uncertainties about its behavior and of external disturbances. Tracking of set points is often required for lower-level control loops, but at the system level in most cases, this is not the primary concern and may even be counterproductive. In this article,

the use of dynamic online optimization on a moving finite horizon to realize optimal system performance is discussed. By real-time optimization, a performance-oriented or economic cost criterion is minimized or maximized over a finite horizon, while the usual control specifications enter as constraints but not as set points. This approach integrates the computation of optimal set-point trajectories and of the regulation to these trajectories.

Keywords

MPC · Performance optimizing control ·
Process control · Integrated RTO and control

Introduction

From an applications point of view, the purpose of automatic feedback control (and that of manual control as well) in many cases is *not* primarily to keep the controlled variables at their set points as well as possible, or to track dynamic set-point changes, but to operate the controlled system such that its *performance* is optimized in the presence of disturbances and uncertainties, by exploiting the information gained in real time from the available measurements. This holds generally for the higher control layers in the process industries but similarly for many other applications. Suppose that for example, the availability of cooling water at a lower temperature than assumed as a worst case during plant design enables plant operation at a higher throughput. In this case what sense does it make to enforce the nominal operating point by tight feedback control? For a combustion engine, the goal is to achieve the desired torque with minimum consumption of fuel. For a cooling system, the goal is to keep the temperature of the goods or of a room within certain bounds with minimum consumption of energy, possibly weighted against the wear of the equipment. To regulate some variables to their set points may help to achieve these goals, but it is not the real performance target for the overall system. Feedback control loops

therefore usually are part of control hierarchies that establish good performance of the overall system and the meeting of constraints on its operation.

There are four main approaches to the integration of feedback control with system performance optimization:

- Choice of regulated variables such that, implicitly via the regulation of these variables to their set points, the performance of the overall system is close to optimal (see the entry on Control Structure Selection by Skogestad);
 - Tracking of necessary conditions of optimality where variables which determine the optimal operating policy are kept at or close to their constraints. This is a widespread approach especially in chemical batch processes where, e.g., the feeding of reactants is such that the maximum cooling power available is used (Finkler et al. 2014); see also the entry on Optimizing Control of Batch Processes by Bonvin.
- In these two approaches, the choice of the optimal set points or constraints to be tracked is done offline, and they are then implemented by the feedback layer of the process control hierarchy (see the entry on Control Hierarchy of Large Processing Plants by de Prada).
- Combination of a regulatory (tracking) feedback control layer with an optimization of the set points or system trajectories (called real-time optimization in the process industries) (see the entry on Real-time Optimization by Trierweiler);
 - Reformulation of model-predictive control such that the control target is not the tracking of references but the optimization of the system performance over a finite horizon, taking constraints of system variables or inputs into account directly within the online optimization. Here, the optimization is performed with a dynamic model, in contrast to performing steady-state optimization in real-time optimization or in the choice of self-optimizing control structures.

All four approaches are currently applied in the process industries. Tracking of necessary conditions of optimality is usually designed based on process insight rather than on a rigorous analysis, and the same holds for the selection of regulatory control structures. The combination of RTO with a regulatory control layer (often model-predictive control, MPC) is applied in particular to petrochemical plants. The last approach, performance optimizing control, has found applications so far mostly in semi-batch polymerization processes where the batch time is minimized under constraints on the reactor temperature (e.g., see Finkler et al. 2014). It is challenging in terms of the required models and algorithms and computing power, but it also has the highest potential in terms of the resulting performance of the controlled system. Moreover, it is structurally simple and easier to tune because the natural performance specification does not have to be translated into controller tunings, weights in MPC cost functions, etc. Therefore the idea of direct model-based performance optimizing control has found much attention in process control in recent years.

The four approaches above are discussed in more detail below. We also provide some historical notes and outline some areas of continuing research.

Performance Optimization by Regulation to Fixed Set Points

Morari et al. (1980) stated that the objective in the synthesis of a control structure is “to translate the economic objectives into process control objectives.” A subgoal in this “translation” is to select the regulatory control structure of a process such that steady-state optimality of process operations is realized to the maximum extent possible by driving the selected controlled variables to suitably chosen set points. A control structure with this property was termed “self-optimizing control” by Skogestad (2000). It should adjust the manipulated variables by keeping a function of the measured variables constant such that the process is operated at the economically optimal steady state in the presence of disturbances.

Ideally, in the steady state, a similar performance is obtained as it would be realized by optimizing the stationary values of the operational degrees of freedom of the system for known disturbances d and a perfect model. By regulating the controlled variables to their set points at the steady state in the presence of disturbances, a mapping $u = f(y_{\text{set}}, d)$ is implicitly realized which should be an approximation of the performance optimizing inputs $u_{\text{opt}}(d)$. The choice of the self-optimizing control structure takes only the steady-state performance into account, not the dynamic reaction of the controlled plant. An extension of the approach to include also the dynamic behavior can be found in Pham and Engell (2011).

Tracking of Necessary Conditions of Optimality

Very often, the optimal operation of a system in a certain phase of its evolution or under certain conditions is defined by some variables being at their constraints. If these variables are known and the conditions can be monitored, a switching control structure can be built that keeps the (possibly changing) set of critical variables at their constraints despite inaccuracies of the model, external disturbances, etc. In fact it turns out that such control schemes can, in the case of varying parameters and in the presence of disturbances, perform as good as sophisticated model-based optimization schemes (e.g., see Finkler et al. 2013).

Performance Optimization by Steady-State Optimization and Regulation

A well-established approach to create a link between regulatory control and the optimization of the performance of a system is to compute the set points of the controllers by an optimization layer. In process operations, this layer is called real-time optimization (RTO) (e.g., see Marlin and Hrymak (1997) and the references therein). An RTO system is a model-based, upper-

level control system that is operated in closed loop and provides set points to the lower-level control systems in order to maintain the process operation as close as possible to the economic optimum. It usually comprises an estimation of the plant states and plant parameters from the measured data and an economic or otherwise performance-related optimization of the operating point using a detailed nonlinear steady-state model.

As the RTO system employs a stationary process model and the optimization is only performed if the plant is approximately in a steady state, the time between successive RTO steps must be large enough for the plant to reach a new steady state after the last commanded move.

This structure is based upon a separation of concerns and of timescales between the RTO system and the process control system. The RTO system optimizes the system economics on a medium timescale (shifts to days), while the control system provides tracking and disturbance rejection on shorter timescales from seconds to hours.

As a an approximation to real-time optimization with a nonlinear rigorous plant model, in many MPC implementations nowadays, an optimization of the steady-state values based on the linear model that is used in the MPC controller is implemented. Then the gain matrix of the model must be estimated carefully to obtain good results.

Performance Optimizing Control

Model-predictive control has become the standard solution for demanding control problems in the process industries (Qin and Badgwell 2003) and increasingly is used also in other domains. The core idea is to employ a model to predict the effect of the future manipulated variables on the future controlled variables over a finite horizon and to use optimization to determine sequences of inputs which minimize a cost function over the so-called prediction horizon. In the unconstrained case with linear plant model and a quadratic cost function, the optimal control moves can

be computed by a closed-form solution. When constraints on inputs, outputs, and possibly also state variables are present, for a quadratic cost function and linear plant model, the optimization problem becomes a quadratic program (QP) that has to be solved in real time.

When the system dynamics are nonlinear and linear models are not sufficiently accurate over the operating region of interest, as is the case in many chemical processes, nonlinear model-predictive control which is based on nonlinear models of the process dynamics provides superior performance and therefore has met increasing interest both in theory and in practice. The classical formulation of nonlinear model-predictive tracking control (TC) is:

$$\min_u \varphi_{TC}(\hat{y}, u)$$

$$\varphi_{TC} = \sum_{n=1}^N \left(\sum_{i=1}^P \gamma_{n,i} (y_{n,ref}(k-i) - \hat{y}_n(k+i))^2 \right) + \sum_{l=1}^R \left(\sum_{j=1}^M \alpha_{l,j} \Delta u_l^2(k+j) \right)$$

s.t.

$$x(i+1) = f(x(i), z(i), u(i), i), \quad i = k, \dots, k+P$$

$$0 = g(x(i), z(i), u(i), i), \quad i = k, \dots, k+P$$

$$y(i+1) = h(x(i+1), u(i)), \quad i = k, \dots, k+P$$

$$x_{\min} \leq x(i) \leq x_{\max}, \quad i = k, \dots, k+P$$

$$y_{\min} \leq \hat{y}(i) \leq y_{\max}, \quad i = k, \dots, k+P$$

$$u_{\min} \leq u(i) \leq u_{\max}, \quad i = k, \dots, k+M$$

$$-\Delta u_{\min} \leq \Delta u(i) \leq \Delta u_{\max}, \quad i = k, \dots, k+M$$

$$u(i) = u(i-1) + \Delta u(i), \quad i = k, \dots, k+M$$

$$u(i) = u(k+M), \quad \forall i > k+M$$

Here f and g represent the plant model in the form of a system of differential-algebraic equations and h is the output function. P is the length of the prediction horizon, and M is the length of the control horizon; $y_1, \dots, y_N$ are the predicted control outputs; $u_1, \dots, u_R$ are the

control inputs. α and γ represent the weights on the control inputs and the control outputs, respectively. y_{ref} refers to the set point or the desired output trajectory; $\hat{y}(i)$ are the corrected model predictions. N is number of the controlled outputs; R is the number of the control inputs. Compensation for plant model mismatch and unmeasured disturbances is usually done using the bias correction equations:

$$d(k) = y^{\text{meas}}(k) - y(k),$$

$$\hat{y}(k+i) = y(k+i) + d(k), \quad i = k, \dots, k+P$$

The idea of direct performance optimizing control (POC) is to replace this formulation by a performance-related objective function:

$$\begin{aligned} \min_u \varphi_{POC}(y, u) \\ \varphi_{POC} = \sum_{l=1}^R \left(\sum_{j=1}^M \alpha_{l,j} \Delta u_l^2(k+j) \right) \\ - \left(\sum_{i=1}^P \beta_i \psi(k+i) \right). \end{aligned}$$

Here $\psi(k+i)$ represents the value of the performance cost criterion at the time step $[k+i]$. The optimization of the future control moves is subject to the same constraints as before. In addition, instead of reference tracking, constraints are formulated for all outputs that are critical for the operation of the system or its performance, e.g., product quality specifications or limitations of the equipment. In contrast to reference tracking, these constraints usually are one-sided (inequalities) or define operation bands. By this formulation, e.g., the production revenues can be maximized online over a finite horizon, considering constraints on product purities and waste streams. Feedback enters into the computation by the initialization of the model with a new initial state that is estimated from the available measurements of system variables and by the bias correction. Thus direct performance optimizing control realizes an online optimization of all operational degrees of freedom in a feedback

structure without tracking of a priori fixed set points or reference trajectories. The regularization term that penalizes control moves is added to the purely economic objective function to obtain smoother solutions.

This approach has several advantages over a combined steady-state optimization/ linear MPC scheme:

- Immediate reaction to disturbances, no waiting for the plant to reach a steady state is required.
- “Overregulation” is avoided – no variables are forced to fixed set points and all degrees of freedom can be used to improve the (economic) performance of the plant.
- Performance goals and process constraints do not have to be mapped to a control cost that defines a compromise between different goals. In this way, the formulation of the optimization problem and the tuning are facilitated compared to achieving good performance by tuning of the weights of a tracking formulation.
- More constraints than available manipulated variables can be handled as well as more manipulated variables than variables that have to be regulated.
- No inconsistency arises from the use of different models on different layers.
- The overall scheme is structurally simple.

Similar to any NMPC controller that is designed for reference tracking, a successful implementation requires careful engineering such that as many uncertainties as possible are compensated by simple feedback controllers and only the key dynamic variables are handled by the optimizing controller based on a rigorous model of the essential dynamics and of the stationary relations of the plant.

History and Examples

The idea of economic or performance optimizing control originated from the process control

community. The first papers on directly integrating economic considerations into model-predictive control (Zanin et al. 2000) proposed to achieve a better economic performance by adding an economic term to a classical tracking performance criterion and applied this to the control of a fluidized bed catalytic cracker. Helbig et al. (2000) discussed different ways to integrate optimization and feedback control including direct dynamic optimization for the example of a semi-batch reactor. Toumi and Engell (2004) and Erdem et al. (2004) demonstrated that online performance optimizing control schemes for simulated moving bed (SMB) chromatographic separations in lab-scale SMB processes are periodic processes and constitute prototypical examples where additional degrees of freedom can be used to simultaneously optimize *system* performance and to meet product specifications. Bartusiak (2005) already reported industrial applications of carefully engineered performance optimizing NMPC controllers.

Direct performance optimizing control was suggested as a promising general new control paradigm for the process industries by Rolandi (2005), Engell (2006, 2007), Rawlings and Amrit (2009), and others. Meanwhile it has been demonstrated in many simulation studies that direct optimization of a performance criterion can lead to superior economic performance compared to classical tracking (N)MPC (e.g., Ochoa et al. (2010) for a bioethanol process, Idris and Engell (2012) for a reactive distillation column).

An application study for the drying of milk powder can be found in Petersen et al. (2017). Haßkerl et al. (2018) demonstrated performance-optimizing control for a real pilot-scale reactive distillation process that performs a complex trans-esterification process based upon a rigorous process model consisting of 186 differential states and 288 algebraic equations. It was shown that the performance optimizing controller can drive the process to the optimum quickly and can perform a transition between two different main products automatically and with minimized losses.

Further Issues

Modeling and Robustness

In a direct performance optimizing control approach, sufficiently accurate dynamic nonlinear process models are needed. While in the process industries nonlinear steady-state models are nowadays available for many processes because they are built and used extensively in the process design phase, there is still a considerable additional effort required to formulate, implement, and validate nonlinear dynamic process models. The effort for rigorous or semi-rigorous modeling usually dominates the cost of an advanced control project. To use data-based black box or gray box models may be effective for regulatory control where the model only has to capture the essential dynamics of the plant near an operating point, but it seems to be less suitable for optimizing control where the optimal plant performance is aimed at, and hence the operating point varies dynamically.

Model inaccuracies always have to be taken into account. They may not only lead to suboptimal performance but also can cause that the constraints even on measured variables cannot be met in the future because of an insufficient back-off from the constraints. A new approach to deal with uncertainties about model parameters and future influences on the process is multistage MPC which is based on optimization with recourse. Here the model uncertainties are represented by a set of scenarios of parameter variations, and the future availability of additional information is taken into account. It has been demonstrated that this is an effective tool to handle model uncertainties and to automatically generate the necessary back-off without being overly conservative Lucia et al. (2013). An application to a complex biotechnological process with significant model uncertainty can be found in (Hebing et al. 2020). Here two structurally different models, based on classical Monod-type kinetics, the other on a gray box model, are employed.

State Estimation

For the computation of economically optimal process trajectories based upon a rigorous non-

linear process model, the state variables of the system at the beginning of the prediction horizon must be known. As not all states will be measured in a practical application, state estimation is a key ingredient of a performance optimizing controller. Extended Kalman filters are the standard solution used in the process industries. If the nonlinearities are significant, unscented Kalman filters or particle filters may be used. A novel approach is to formulate the state estimation problem also as an optimization problem on a moving horizon (Rao et al. 2003). The estimation of some important varying unknown model parameters can be included in this formulation. As accurate state estimation is at least as critical for the performance of the closed-loop system as the exact tuning of the optimizing controller, attention must be paid to the investigation of the performance of state estimation schemes in realistic situations with model-plant mismatch.

Stability

Optimization of a cost function over a finite horizon in general assures neither optimality of the complete trajectory beyond this horizon nor stability of the closed-loop system. Closed-loop stability has been addressed extensively in the theoretical research in nonlinear model-predictive control. Stability can be assured by a proper choice of the stage cost within the prediction horizon and the addition of a cost on the terminal state and the restriction of the terminal state to a suitable set. In performance optimizing MPC, there is no a priori known steady state to which the trajectory should converge, and the economic cost function may not satisfy the usual conditions for closed-loop stability, e.g., because it only involves some of the inputs and not necessarily the states of the system under control. In recent years, important results on closed-loop stability guaranteeing formulations have been obtained, involving terminal constraints or a quasi-infinite horizon (Diehl et al. 2011; Angeli et al. 2012; Grüne 2013).

Reliability and Transparency

Nowadays quite large nonlinear dynamic optimization problems can be solved in real time,

not only for slow processes as they are found in the chemical industry but also in mechatronics and automotive control. So this issue does no longer prohibit the application of a performance optimizing control scheme to complex systems. A practically very important limiting issue however is that of reliability and transparency. It is difficult to guarantee that a nonlinear optimizer will always provide a solution which at least satisfies the constraints and gives a reasonable performance for all possible input data. While for an RTO scheme an inspection of the commanded set points by the operators usually will be feasible, this is less likely to be realistic in a dynamic situation. Hence automatic result filters are necessary as well as a backup scheme that stabilizes the process in the case where the result of the optimization is not considered safe. In the process industries, the operators will continue to supervise the operation of the plant in the foreseeable future, so a control scheme that includes performance optimizing control must be structured into modules, the outputs of which can still be understood by the operators so that they build up trust in the optimization. Good operator interfaces that display the predicted moves and the predicted reaction of the plant and enable comparisons with the operators' intuitive strategies are believed to be essential for practical success.

Effort vs. Performance

The gain in performance by a more sophisticated control scheme always has to be traded against the increase in cost due to the complexity of the control scheme – a complex scheme will not only cause cost for its implementation, but it will need more maintenance by better qualified people than a simple one. If a carefully chosen standard regulatory control layer leads to a close-to-optimal operation, there is no need for optimizing control. If the disturbances that affect profitability and cannot be handled well by the regulatory layer (in terms of economic performance) are slow, the combination of regulatory control and RTO is sufficient. In a more dynamic situation or for complex nonlinear multivariable plants, the idea of direct performance optimizing control should

be explored and implemented if significant gains can be realized in simulations.

Model-Free Reinforcement Learning-Based Control for Continuous-Time Systems

Kyriakos G. Vamvoudakis

The Daniel Guggenheim School of Aerospace Engineering, Georgia Institute of Technology, Atlanta, GA, USA

Abstract

This book entry discusses model-free reinforcement learning algorithms based on a continuous-time Q-learning framework. The presented schemes solve infinite-horizon optimization problems of linear time-invariant systems with completely unknown dynamics and single or multiple players/controllers. We first formulate the appropriate Q-functions (action-dependent value functions) and the tuning laws based on actor/critic structures for several cases including optimal regulation; Nash games, multi-agent systems, and cases with intermittent feedback.

Keywords

Q-learning · Games · Optimal control · Autonomy · Model-free · Intermittent learning

Introduction

Machine learning has been used for enabling adaptive autonomy (Vamvoudakis et al. 2015). Machine learning is grouped, in supervised, unsupervised, or reinforcement (RL), depending on the amount and quality of feedback about the system or task. In supervised learning, the feedback information provided to learning algorithms is a labeled training data set, and the objective is to build the system model representing the learned relation between the input, output, and system parameters. In unsupervised learning, no feedback information is provided to the algorithm, and the objective is to classify the

sample sets to different groups based on the similarity between the input samples. Finally, RL is a goal-oriented learning tool wherein the agent or decision-maker learns a policy to optimize a long-term reward by interacting with the environment. At each step, an RL agent gets evaluative feedback about the performance of its action, allowing it to improve the performance of subsequent actions (Sutton and Barto 2018; Bertsekas and Tsitsiklis 1996; Cao 2007; Liu et al. 2017).

In a control engineering context, RL bridges the gap between traditional optimal control and adaptive control algorithms (Krstić and Kanellakopoulos 1995; Tao et al. 2003; Ioannou and Fidan 2006; Hovakimyan and Cao 2010; Vamvoudakis et al. 2017b). The goal is to learn the optimal policy and value function for a potentially uncertain physical system. Unlike traditional optimal control, RL finds the solution to the Hamilton-Jacobi-Bellman (HJB) equation online in real time. On the other hand, unlike traditional adaptive controllers, which are not usually designed to be optimal in the sense of minimizing cost functionals, RL algorithms are optimal. This has motivated control system researchers to enable adaptive autonomy in an optimal manner by developing RL-based controllers. In continuous-time linear systems with multiple decision-makers and quadratic costs, one has to rely on solving complicated matrix Riccati equations that require complete knowledge of the system matrices and needs to be solved offline and then implemented online in the controller. In the era of complex and big data systems, modeling the processes exactly is most of the time infeasible, and offline solutions make the systems vulnerable to parameter changes (drift).

Q-learning is a model-free RL technique developed primarily for discrete-time systems (Watkins 1989). It learns an action-dependent value function that ultimately gives the expected utility of taking a given action in a given state and following the optimal policy thereafter. When such an action-dependent value function is learned, the optimal policy can be computed easily. The *biggest strength* of Q-learning is that

it is model-free. It has been proven in Watkins (1989) that for any finite Markov decision process, Q-learning eventually finds an optimal policy. In complex-systems, Q-learning needs to store a lot of data, which makes the algorithm infeasible. This problem can be solved effectively by using adaptation techniques. Specifically, Q-learning can be improved by using the universal function approximation property that allows us to solve difficult optimization problems online and forward in time. This makes it possible to apply the algorithm to larger problems, even when the state space is continuous and infinitely large.

The purpose of this entry is to show how to solve optimal control problems (single player games), multiplayer games with intermittent and continuous feedback, online by Q-learning in real time using data measured along the trajectories without requiring any information of the dynamics. It provides a truly model-free and dynamic framework for decision-making, since learning agents can change their objectives or optimality criteria on the fly.

Notation We denote $\underline{\lambda}(A)(\bar{\lambda}(A))$ as the minimum (maximum) eigenvalue of a matrix A . The half-vectorization, $\text{vech}(A)$, of a symmetric $n \times n$ matrix A is the $n(n+1)/2$ column vector obtained by vectorizing only the upper (or lower) triangular part of A , $\text{vech}(A) = [A_{1,1} \cdots A_{n,1} \ A_{2,2} \cdots A_{n,2} \cdots A_{n-1,n-1} \ A_{n-1,n} \ A_{n,n}]^T$. Finally, $(\cdot)^*$ symbolizes the optimal solution.

Optimal Regulation

The infinite horizon optimal control problem is formulated as a Q-learning (model-free) problem by using a quadratic in the state and control parametrization. An integral reinforcement learning approach will be used to design and derive tuning formulas for a critic approximator estimating the action-dependent value of the Q-function and for an actor approximator estimating the optimal control. The actor and the critic approximators are tuned simultaneously by measuring

information along the state and the control trajectories *without the need of an initial admissible (i.e., stabilizing) policy*; this is in contrast to existing Q-learning approaches that use sequential policy iteration algorithms which delay the convergence and require admissibility of the initial policy.

Consider the following linear time-invariant continuous-time system,

$$\dot{x}(t) = Ax(t) + Bu(t), \quad x(0) = x_0, \quad t \geq 0, \quad (1)$$

where $x(t) \in \mathbb{R}^n$ is a measurable state vector, $u(t) \in \mathbb{R}^m$ is the control input, and $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$ are the plant and input matrices, respectively, that will be considered uncertain/unknown. It is assumed that the pair (A, B) is controllable. Our goal is to find a controller u that minimizes a cost functional of the form, $J(x(0); u) = \frac{1}{2} \int_0^\infty (x^T M x + u^T R u) dt$ with user-defined matrices $M \geq 0$, $R > 0$ of appropriate dimensions and $(\sqrt{M}, A)$ detectable.

The ultimate goal is to find the optimal value function V^* defined by,

$$V^*(x(t)) := \min_u \int_t^\infty \frac{1}{2} (x^T M x + u^T R u) d\tau, \quad \forall t, \quad (2)$$

given (1) but without any information of the system dynamics.

Model-Free Formulation

The value function needs to be parametrized as a function of the state x and the control u to represent the Q-function. The optimal value given by (2) after adding the Hamiltonian can be written as the following advantage function $Q(x, u) : \mathbb{R}^{n+m} \rightarrow \mathbb{R}$,

$$\begin{aligned} Q(x, u) := & V^*(x) + \frac{1}{2} x^T P (Ax + Bu) \\ & + \frac{1}{2} (Ax + Bu)^T P x + \frac{1}{2} u^T R u \\ & + \frac{1}{2} x^T M x, \quad \forall x, u, \end{aligned} \quad (3)$$

where the optimal cost is $V^*(x) = \frac{1}{2} x^T P x$ with $P > 0$.

The Q-function (3) can be written in a compact quadratic in the state x and control u form as follows,

$$\begin{aligned} Q(x, u) &= \frac{1}{2} U^T \begin{bmatrix} P + M + PA + A^T P & PB \\ B^T P & R \end{bmatrix} U \\ &:= \frac{1}{2} U^T \begin{bmatrix} Q_{xx} & Q_{xu} \\ Q_{ux} & Q_{uu} \end{bmatrix} U \\ &:= \frac{1}{2} U^T \bar{Q} U, \quad \forall x, u, \end{aligned} \quad (4)$$

where $U := [x^T u^T]^T$, $Q_{xx} = P + M + PA + A^T P$, $Q_{xu} = PB$, $Q_{ux} = Q_{xu}^T = B^T P$, $Q_{uu} = R$, and $\bar{Q} = \begin{bmatrix} Q_{xx} & Q_{xu} \\ Q_{ux} & Q_{uu} \end{bmatrix} \in \mathbb{R}^{(n+m) \times (n+m)}$.

A model-free formulation can be found by solving $\frac{\partial Q(x, u)}{\partial u} = 0$ to write,

$$u^*(x) = \arg \min_u Q(x, u) = -Q_{uu}^{-1} Q_{ux} x. \quad (5)$$

The critic approximator will approximate the Q-function (4), and the actor approximator will approximate the optimal controller (5). Specifically $Q^*(x, u^*)$ can be written as,

$$\begin{aligned} Q^*(x, u^*) &= \frac{1}{2} U^T \begin{bmatrix} Q_{xx} & Q_{xu} \\ Q_{ux} & Q_{uu} \end{bmatrix} U \\ &:= \frac{1}{2} \text{vech}(\bar{Q})^T (U \otimes U) \end{aligned} \quad (6)$$

where $\text{vech}(\bar{Q}) \in \mathbb{R}^{\frac{1}{2}(n+m)(n+m+1)}$ a half-vectorization of the matrix $\bar{Q}$ where the off-diagonal elements are taken as $2\bar{Q}_{ij}$ and $\otimes$ denotes the Kronecker product quadratic polynomial basis vector with the elements $\{U_i U_j\}_{i=1 \dots n+m; j=1 \dots n+m}$.

By denoting as $W_c := \frac{1}{2} \text{vech}(\bar{Q})$, we can write (6) in a compact form as $Q^*(x, u^*) = W_c^T (U \otimes U)$, with $W_c \in \mathbb{R}^{\frac{1}{2}(n+m)(n+m+1)}$ the ideal weights given as $\text{vech}(Q_{xx}) := W_c[1 : \frac{n(n+1)}{2}]$, $\text{vech}(Q_{xu}) := W_c[\frac{n(n+1)}{2} + 1 : \frac{n(n+1)}{2} + nm]$ and $\text{vech}(Q_{uu}) := W_c[\frac{n(n+1)}{2} + 1 + nm : \frac{(n+m)(n+m+1)}{2}]$.

Since the ideal weights for computing Q^* and u^* are unknown, one must consider the following *weight estimates*. The critic approximator with $\hat{W}_c := \text{vech}(\hat{Q})$ can be written as,

$$\hat{Q}(x, u) = \hat{W}_c^T (U \otimes U),$$

where $\hat{W}_c \in \mathbb{R}^{\frac{1}{2}(n+m)(n+m+1)}$ are the estimated weights and $U := [x^T u^T]^T$. Similarly the actor approximator can be expressed as,

$$\hat{u}(x) = \hat{W}_a^T x,$$

where $\hat{W}_a \in \mathbb{R}^{n \times m}$ are the weight estimates; note also that the state x is serving as an activation function for the action approximator.

We shall define an error $e \in \mathbb{R}$ that we would like to eventually drive to zero by picking appropriately the tuning law for $\hat{W}_c$. In order to do that, we shall take into consideration the integral Bellman equation, and using actual values for the Q-function, we can rewrite the integral Bellman error as,

$$\begin{aligned} e &:= \hat{Q}(x(t), u(t)) - \hat{Q}(x(t-T), u(t-T)) \\ &\quad + \frac{1}{2} \int_{t-T}^T (x^T M x + u^T R u) d\tau \\ &= \hat{W}_c^T (U(t) \otimes U(t)) \\ &\quad + \frac{1}{2} \int_{t-T}^T (x^T M x + u^T R u) d\tau \\ &\quad - \hat{W}_c^T (U(t-T) \otimes U(t-T)). \end{aligned}$$

Now for the actor approximator, we can define the error $e_a \in \mathbb{R}^m$ as follows, $e_a := \hat{W}_a^T x + \hat{Q}_{uu}^{-1} \hat{Q}_{ux} x$, where the values of $\hat{Q}_{uu}^{-1}$ and $\hat{Q}_{ux}$ are going to be extracted from the vector $\hat{W}_c$. Now we shall find tuning updates for $\hat{W}_c$ and $\hat{W}_a$ such that the errors e and e_a go to zero.

By following adaptive control techniques, we can define the squared norm of errors e and e_a as,

$$K_1 = \frac{1}{2} \|e\|^2, \quad (7)$$

$$K_2 = \frac{1}{2} \|e_a\|^2. \quad (8)$$

The estimate of $\hat{W}_c$ (in order to guarantee that $e \rightarrow 0$ and $\hat{W}_c \rightarrow W_c$) for the critic weights can be constructed by applying gradient descent in (7), using the chain rule and normalizing (following adaptive control theory) as,

$$\dot{\hat{W}}_c = -\alpha_c \frac{\partial K_1}{\partial \hat{W}_c} = -\alpha_c \frac{\sigma}{(1 + \sigma^T \sigma)^2} e^T,$$

where $\sigma := U(t) \otimes U(t) - U(t-T) \otimes U(t-T)$ and $\alpha_c \in \mathbb{R}^+$ is a constant gain that determines the speed of convergence.

Similarly, the gradient descent estimate of $\hat{W}_a$ for the actor weights can be constructed by differentiating (8) as,

$$\dot{\hat{W}}_a = -\alpha_a \frac{\partial K_2}{\partial \hat{W}_a} = -\alpha_a x e_a^T,$$

where $\alpha_a \in \mathbb{R}^+$ is a constant gain that determines the speed of convergence.

Algorithm 1 gives the pseudocode for the approach.

Algorithm 1 Q-learning for optimal regulation

- 1: **procedure**
 - 2: Start with initial conditions $x(0)$, and random initial weights $\hat{W}_c(0)$, $\hat{W}_a(0)$, for the critic and the actor.
 - 3: Propagate t , $x(t)$.
 - 4: Propagate $\hat{W}_c(t)$, $\hat{W}_a(t)$.
 - 5: Compute the Q-function $\hat{Q}$ and the optimal control $\hat{u}$.
 - 6: **end procedure**
-

More details about model-free optimal regulation are given in Vamvoudakis (2017b), and a model-free kinodynamic motion planning framework is provided in Kontoudis and Vamvoudakis (2019).

Nash Games

Consider N players playing in a Nash dynamic game. The N agent/decision-makers can be non-cooperative and also can cooperate in teams.

Each of the agents has access to the full state of the system. Since solving Nash game requires complete knowledge of the centralized system dynamics and complicated offline computation, we present a completely mode-free algorithm to solve the coupled Riccati equations arising in multi-player non-zero sum Nash games in deterministic systems. A parametrized Q-function is derived for every of the N -players in the game that depends on the state and the control inputs of all the players. Then we derive mode-free controllers based on the Q-function parametrization, and then we use $2N$ -universal approximators such to approximate the cost and the control of every player, by using, namely, a critic and an actor network.

Consider the following linear time-invariant continuous-time system,

$$\dot{x}(t) = Ax(t) + \sum_{j=1}^N B_j u_j(t), \quad x(0) = x_0, \quad t \geq 0, \quad (9)$$

where $x(t) \in \mathbb{R}^n$ is a measurable state vector, $u_j(t) \in \mathbb{R}^{m_j}$, $j \in \mathcal{N} := \{1, \dots, N\}$ is each control input (or player), and $A \in \mathbb{R}^{n \times n}$, $B_j \in \mathbb{R}^{n \times m_j}$, $j \in \mathcal{N}$ are the plant and input matrices, respectively, that will be considered uncertain/unknown. It is assumed that the unknown pairs (A, B_j) , $\forall j \in \mathcal{N}$ are controllable. The ultimate goal is to find the optimal value functions V_i^* , $\forall i \in \mathcal{N}$ defined by,

$$V_i^*(x(t)) := \min_{u_i} \int_t^\infty \frac{1}{2} \left(x^T H_i x + \sum_{j=1}^N u_j^T R_{ij} u_j \right) d\tau, \quad \forall t, \quad (10)$$

with user-defined matrices $H_i \succeq 0$, $R_{ij} \succ 0$, $\forall i, j \in \mathcal{N}$ of appropriate dimensions and

$(\sqrt{H_i}, A)$, $\forall i \in \mathcal{N}$ are detectable, and without any information of the system matrices A and B_i , $\forall i \in \mathcal{N}$ that appear in (9).

Model-Free Formulation

The value functions need to be parametrized as a function of the state x and the controls u_i , $\forall i \in \mathcal{N}$ to represent the Q-function for each player in the game. The optimal value given by (10) after adding the Hamiltonian can be written as the following advantage function $Q_i(x, u_i, u_{-i}) : \mathbb{R}^{n+\sum_{j=1}^N m_j} \rightarrow \mathbb{R}$,

$$\begin{aligned} Q_i(x, u_i, u_{-i}) &:= V_i^*(x) + \frac{1}{2}x^T P_i \left(Ax + \sum_{j=1}^N B_j u_j \right) \\ &\quad + \frac{1}{2} \left(Ax + \sum_{j=1}^N B_j u_j \right)^T P_i x \\ &\quad + \frac{1}{2} \sum_{j=1}^N u_j^T R_{ij} u_j + \frac{1}{2}x^T H_i x, \\ &\quad \forall x, u_i, u_{-i}, \forall i \in \mathcal{N}, \end{aligned}$$

where the optimal cost is $V_i^*(x) = x^T P_i x$ with $P_i \succ 0$.

Each player's Q-function can be written in a compact quadratic in the state x and controls u_i , $i \in \mathcal{N}$ form as shown next.

$$\begin{aligned} Q_i(x, u_i, u_{-i}) &= \frac{1}{2} U_i^T \begin{bmatrix} P_i + H_i + P_i A + A^T P_i & P_i B_i & P_i B_1 & \cdots & P_i B_{i-1} & P_i B_{i+1} & \cdots & P_i B_N \\ B_i^T P_i & R_{ii} & 0 & \cdots & \cdots & \cdots & \cdots & 0 \\ B_1^T P_i & 0 & R_{i1} & 0 & \cdots & \cdots & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots \\ B_{i-1}^T P_i & 0 & \cdots & \cdots & R_{ii-1} & 0 & \cdots & 0 \\ B_{i+1}^T P_i & 0 & \cdots & \cdots & \cdots & R_{ii+1} & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ B_N^T P_i & 0 & \cdots & \cdots & \cdots & \cdots & \cdots & R_{iN} \end{bmatrix} U_i \\ &:= \frac{1}{2} U_i^T \begin{bmatrix} Q_{xx}^i & Q_{xu_i}^i & Q_{xu_1}^i & \cdots & Q_{xu_{i-1}}^i & Q_{xu_{i+1}}^i & \cdots & Q_{xu_N}^i \\ Q_{u_i x}^i & Q_{u_i u_i}^i & 0 & \cdots & \cdots & \cdots & \cdots & 0 \\ Q_{u_1 x}^i & 0 & Q_{u_1 u_1}^i & \cdots & \cdots & \cdots & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots \\ Q_{u_{i-1} x}^i & 0 & \cdots & \cdots & Q_{u_{i-1} u_{i-1}}^i & 0 & \cdots & 0 \\ Q_{u_{i+1} x}^i & 0 & \cdots & \cdots & \cdots & Q_{u_{i+1} u_{i+1}}^i & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ Q_{u_N x}^i & 0 & \cdots & \cdots & \cdots & \cdots & \cdots & Q_{u_N u_N}^i \end{bmatrix} U_i \\ &:= \frac{1}{2} U_i^T \bar{Q}^i U_i, \quad \forall x, u_i, \forall i \in \mathcal{N}, \end{aligned}$$

where $U_i := [x^T \ u_i^T \ u_1^T \ \cdots \ u_{i-1}^T \ u_{i+1}^T \ \cdots \ u_N^T]^T$.

A model-free formulation of the best policies can be found by solving $\frac{\partial Q_i(x, u_i, u_{-i})}{\partial u_i} = 0$ to write,

$$\begin{aligned} u_i^*(x) &= \arg \min_{u_i} Q_i(x, u_i, u_{-i}) \\ &= -(Q_{u_i u_i}^i)^{-1} Q_{u_i x}^i x, \quad \forall i \in \mathcal{N}. \end{aligned}$$

Since we do not know the optimal values, we should estimate Q_i^* and u_i^* with the following actual values for the critic with $\hat{W}_{ic} := \frac{1}{2} \text{vech}(\hat{\bar{Q}}^i)$,

$$\hat{Q}_i(x, u_i, u_{-i}) = \hat{W}_{ic}^T (U_i \otimes U_i), \quad \forall i \in \mathcal{N},$$

where $\hat{W}_{ic} \in \mathbb{R}^{\frac{1}{2}(n+\sum_{j=1}^N m_j)(n+\sum_{j=1}^N m_j+1)}$ are the estimated critic weights and $U_i := [x^T u_i^T u_1^T \cdots u_{i-1}^T u_{i+1}^T \cdots u_N^T]^T$, and for the actor

$$\hat{u}_i(x) = \hat{W}_{ia}^T x, \forall i \in \mathcal{N},$$

where $\hat{W}_{ia} \in \mathbb{R}^{n \times m_i}$ are the estimated actor weights; note also that the state x is serving as an activation function for the action network. The tuning laws for the actor and the critic can be defined in a similar way with the Optimal Regulation part.

Algorithm 2 gives the pseudocode for the approach.

Algorithm 2 Nash Q-learning

- 1: **procedure**
 - 2: Start with initial conditions for every agent $x(0)$ and random initial weights $\hat{W}_{ic}(0), \hat{W}_{ia}(0)$ for the critic and actor approximators.
 - 3: Propagate $t, x(t)$.
 - 4: Propagate $\hat{W}_{ic}(t), \hat{W}_{ia}(t)$.
 - 5: Compute the Q-function $\hat{Q}_i$ and the control $\hat{u}_i$.
 - 6: **end procedure**
-

More details about model-free Nash games are given in Vamvoudakis (2015).

Multi-agent Systems

Multi-agent system interactions are modeled by a fixed strongly connected *graph* $\mathcal{G} = (\mathcal{V}_{\mathcal{G}}, \mathcal{E}_{\mathcal{G}})$ defined by a finite set $\mathcal{V}_{\mathcal{G}} = \{n_1, \dots, n_N\}$ of N nodes that represent agents and a set of edges $\mathcal{E}_{\mathcal{G}} \subseteq \mathcal{V}_{\mathcal{G}} \times \mathcal{V}_{\mathcal{G}}$ that represent interagent information exchange links. The set of *neighbors* of a node n_i is defined as the set of nodes with edges incoming to n_i and is denoted by $\mathcal{N}_i = \{n_j : (n_j, n_i) \in \mathcal{E}_{\mathcal{G}}\}$. The graph is simple (i.e., it has not repeated edges) and has no self-loops (i.e., $(n_i, n_i) \notin \mathcal{E}_{\mathcal{G}}, \forall n_i \in \mathcal{V}_{\mathcal{G}}$). The *connectivity matrix* $\mathcal{A}_{\mathcal{G}} = [\alpha_{ij}]_{N \times N}$ of the graph $\mathcal{G}$ is an $N \times N$ matrix of the form

$$\alpha_{ij} \begin{cases} > 0 & \text{if } (n_j, n_i) \in \mathcal{E}_{\mathcal{G}} \\ = 0 & \text{otherwise,} \end{cases}$$

where α_{ij} is the *weight* associated with the edge $(n_j, n_i) \in \mathcal{E}_{\mathcal{G}}$. The *degree* matrix D of the graph $\mathcal{G}$ is an $N \times N$ diagonal matrix whose i th entry of the main diagonal is the weighted degree $d_i = \sum_{j \in \mathcal{N}_i} \alpha_{ij}$ of node i (i.e., i th row sum of $\mathcal{A}_{\mathcal{G}}$). The number of neighbors of agent i is denoted by $|\mathcal{N}_i|$ which is equal to d_i . A cooperative Q-learning approach is now developed to enable the agents in large networks to synchronize to the behavior of an unknown leader by each optimizing a distributed performance criterion that depends only on a subset of the agents in the network. The novel distributed Q-functions are parametrized as functions of the tracking error, control, and adversarial inputs in the neighborhood. In the developed approach, the agents coordinate with the neighbors in order to pick their minimizing model-free policies in such a way to guarantee convergence to a graphical Nash equilibrium and also attenuation of maximizing worst-case adversarial inputs. A structure of 2-actors and a single critic approximators are used for each agent in the network. This eventually solves the complexity issues that arise in Q-learning. The 2-actors are used to approximate the optimal control input and the worst-case adversarial input, while the critic approximator is used to approximate the optimal cost of each of the coupled optimizations. Effective tuning laws are proposed to solve the model-free cooperative game problem while also guaranteeing closed-loop stability of the equilibrium point.

Consider a networked-system $\mathcal{G}$, consisting of N agents each modeled $\forall i \in \mathcal{N} := \{1, \dots, N\}$ by the following dynamics,

$$\begin{aligned} \dot{x}_i(t) &= Ax_i(t) + B_i u_i(t) + D_i v_i(t), \\ x_i(0) &= x_{i0}, t \geq 0, \end{aligned}$$

where $x_i(t) \in \mathbb{R}^n$ is a measurable state vector available for feedback by each agent and known initial conditions $x_i(0), u_i(t) \in \mathbb{R}^{m_i}, i \in \mathcal{N} := \{1, \dots, N\}$ is each control input (or minimizing player), $v_i(t) \in \mathbb{R}^{l_i}, i \in \mathcal{N} := \{1, \dots, N\}$

is each adversarial input (or maximizing player), and $A \in \mathbb{R}^{n \times n}$, $B_i \in \mathbb{R}^{n \times m_i}$, $D_i \in \mathbb{R}^{n \times l_i}$, $i \in \mathcal{N}$ are the plant, control input, and adversarial input matrices, respectively, that will be considered uncertain/unknown. It is assumed that the unknown pairs (A, B_i) , $\forall i \in \mathcal{N}$ are stabilizable. We have a total of $2N$ players/controllers that select values for $u_i(t)$, $t \geq 0$, $i \in \mathcal{N}$, and $v_i(t)$, $t \geq 0$, $i \in \mathcal{N}$. The agents in the network seek to cooperatively asymptotically track the state of a leader node/exosystem with dynamics $\dot{x}_L = Ax_L$, i.e., $x_i(t) - x_L(t) \rightarrow 0$, $\forall i \in \mathcal{N}$, while *simultaneously satisfying user-defined distributed performances*. Now we shall proceed to the design of the user-defined *distributed performances*. For that reason, we shall define the following *neighborhood tracking error* for every agent,

$$e_i := \sum_{j \in \mathcal{N}_i} a_{ij}(x_i - x_j) + g_i(x_i - x_L), \forall i \in \mathcal{N}, \quad (11)$$

where $g_i \in \mathbb{R}^+$ is the pinning gain that shows if an agent is pinned to the leader node (i.e., $g_i \neq 0$) and it is non-zero for at least one node.

The dynamics of (11) are given by,

$$\begin{aligned} \dot{e}_i &= Ae_i + (d_i + g_i)(B_i u_i + D_i v_i) \\ &- \sum_{j \in \mathcal{N}_i} a_{ij}(B_j u_j + D_j v_j), \forall i \in \mathcal{N}, \end{aligned} \quad (12)$$

with $e_i \in \mathbb{R}^n$.

The cost functionals associated with each agent $i \in \mathcal{N}$, which depend on the tracking

error e_i , the control u_i , the controls in the neighborhood of agent i given as $u_{\mathcal{N}_i} := \{u_j : j \in \mathcal{N}_i\}$, the adversarial input v_i , and the adversarial inputs in the neighborhood of agent i given as $v_{\mathcal{N}_i} := \{v_j : j \in \mathcal{N}_i\}$, with an ultimate goal to find the distributed optimal value functions V_i^* , $\forall i \in \mathcal{N}$ defined by,

$$\begin{aligned} V_i^*(e_i(t)) &:= \min_{u_i} \max_{v_i} \int_t^\infty \frac{1}{2} \left(e_i^\top H_i e_i \right. \\ &\quad \left. + (u_i^\top R_{ii} u_i - \gamma_{ii}^2 v_i^\top v_i) \right. \\ &\quad \left. + \sum_{j \in \mathcal{N}_i} (u_j^\top R_{ij} u_j - \gamma_{ij}^2 v_j^\top v_j) \right) d\tau, \\ &\quad \forall t, \forall i \in \mathcal{N}, \end{aligned} \quad (13)$$

given (12), but without any information of the system matrices A , B_i , D_i , $\forall i \in \mathcal{N}$ and pinning gains g_i , $\forall i \in \mathcal{N}$ and matrices $H_i \succeq 0$, $R_{ii} \succ 0$, $R_{ij} \succeq 0$, $\forall i, j \in \mathcal{N}$ of appropriate dimensions, $\gamma_{ii}, \gamma_{ij} \in \mathbb{R}^+$, $\forall i \in \mathcal{N}$ and $(\sqrt{H_i}, A)$, $\forall i \in \mathcal{N}$ are detectable.

Model-Free Formulation

The value functions need to be parametrized as functions of the neighborhood tracking error e_i , the controls u_i and $u_{\mathcal{N}_i}$, and the adversarial inputs v_i and $v_{\mathcal{N}_i}$ to represent the distributed Q-function, i.e., sparse cooperative learning, for each agent in the game. The optimal value given by (13) after adding the Hamiltonian can be written as the following distributed advantage function $Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i}) : \mathbb{R}^{n+m_i+l_i+\sum_{j \in \mathcal{N}_i}(m_j+l_j)} \rightarrow \mathbb{R}$,

$$\begin{aligned} &Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i}) \\ &:= V_i^*(e_i) + \frac{\partial V_i^*}{\partial e_i} \left(Ae_i + (d_i + g_i)(B_i u_i + D_i v_i) - \sum_{j \in \mathcal{N}_i} a_{ij}(B_j u_j + D_j v_j) \right) \\ &\quad + \frac{1}{2} \left(e_i^\top H_i e_i + (u_i^\top R_{ii} u_i - \gamma_{ii}^2 v_i^\top v_i) + \sum_{j \in \mathcal{N}_i} (u_j^\top R_{ij} u_j - \gamma_{ij}^2 v_j^\top v_j) \right), \\ &\quad \forall e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i}, \forall i \in \mathcal{N}, \end{aligned}$$

where the optimal cost is $V_i^*(e_i) = \frac{1}{2}e_i^T P_i e_i, \forall i \in \mathcal{N}$.

Each agent's distributed Q-function can be written in a compact quadratic in the neigh-

borhood tracking error e_i , controls $u_i, u_{\mathcal{N}_i}$, and adversarial inputs $v_i, v_{\mathcal{N}_i}$ distributed form as,

$$Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i}) = \frac{1}{2}U_i^T \begin{bmatrix} P_i + H_i + P_i A + A^T P_i & (d_i + g_i)P_i B_i & -\text{row}(a_{ij} P_i B_j)_{j \in \mathcal{N}_i} & (d_i + g_i)P_i D_i & -\text{row}(a_{ij} P_i D_j)_{j \in \mathcal{N}_i} \\ (d_i + g_i)B_i^T P_i & R_{ii} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -\text{col}(a_{ij} B_j^T P_i)_{j \in \mathcal{N}_i} & \mathbf{0} & \text{diag}(R_{ij})_{j \in \mathcal{N}_i} & \mathbf{0} & \mathbf{0} \\ (d_i + g_i)D_i^T P_i & \mathbf{0} & \mathbf{0} & -\gamma_{ii}^2 & \mathbf{0} \\ -\text{col}(a_{ij} D_j^T P_i)_{j \in \mathcal{N}_i} & \mathbf{0} & \mathbf{0} & \mathbf{0} & -\text{diag}(\gamma_{ij}^2)_{j \in \mathcal{N}_i} \end{bmatrix} U_i$$

$$:= \frac{1}{2}U_i^T \begin{bmatrix} Q_{e_i e_i}^i & Q_{e_i u_i}^i & Q_{e_i u_{\mathcal{N}_i}}^i & Q_{e_i v_i}^i & Q_{e_i v_{\mathcal{N}_i}}^i \\ Q_{u_i e_i}^i & Q_{u_i u_i}^i & Q_{u_i u_{\mathcal{N}_i}}^i & Q_{u_i v_i}^i & Q_{u_i v_{\mathcal{N}_i}}^i \\ Q_{u_{\mathcal{N}_i} e_i}^i & Q_{u_{\mathcal{N}_i} u_i}^i & Q_{u_{\mathcal{N}_i} u_{\mathcal{N}_i}}^i & Q_{u_{\mathcal{N}_i} v_i}^i & Q_{u_{\mathcal{N}_i} v_{\mathcal{N}_i}}^i \\ Q_{v_i e_i}^i & Q_{v_i u_i}^i & Q_{v_i u_{\mathcal{N}_i}}^i & Q_{v_i v_i}^i & Q_{v_i v_{\mathcal{N}_i}}^i \\ Q_{v_{\mathcal{N}_i} e_i}^i & Q_{v_{\mathcal{N}_i} u_i}^i & Q_{v_{\mathcal{N}_i} u_{\mathcal{N}_i}}^i & Q_{v_{\mathcal{N}_i} v_i}^i & Q_{v_{\mathcal{N}_i} v_{\mathcal{N}_i}}^i \end{bmatrix} U_i := \frac{1}{2}U_i^T \bar{Q}^i U_i, \forall i \in \mathcal{N},$$

where $U_i := [e_i^T u_i^T u_{\mathcal{N}_i}^T v_i^T v_{\mathcal{N}_i}^T]^T$, $\mathbf{0}$ are zero matrices of appropriate dimensions, $\text{diag}(R_{ij})_{j \in \mathcal{N}_i}$ and $\text{diag}(\gamma_{ij})_{j \in \mathcal{N}_i}$ are stacked diagonal neighborhood matrices, $\text{col}(a_{ij} B_j^T P_i)_{j \in \mathcal{N}_i}$ and $\text{col}(a_{ij} D_j^T P_i)_{j \in \mathcal{N}_i}$ are stacked column neighborhood matrices, and $\text{row}(a_{ij} P_i B_j)_{j \in \mathcal{N}_i}$ and $\text{row}(a_{ij} P_i D_j)_{j \in \mathcal{N}_i}$ are stacked row neighborhood matrices.

A model-free formulation of the minimizing player can be found by solving $\frac{\partial Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i})}{\partial u_i} = 0$ to write,

$$u_i^*(e_i) = \arg \min_{u_i} Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i})$$

$$= -(Q_{u_i u_i}^i)^{-1} Q_{u_i e_i}^i e_i, \forall i \in \mathcal{N},$$

and a model-free formulation of the maximizing player can be found by solving $\frac{\partial Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i})}{\partial v_i} = 0$ to write,

$$v_i^*(e_i) = \arg \max_{v_i} Q_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i})$$

$$= -(Q_{v_i v_i}^i)^{-1} Q_{v_i e_i}^i e_i, \forall i \in \mathcal{N}.$$

The critic approximator is given by,

$$\hat{Q}_i(e_i, u_i, u_{\mathcal{N}_i}, v_i, v_{\mathcal{N}_i}) = \hat{W}_{ic}^T (U_i \otimes U_i), \forall i \in \mathcal{N},$$

where $\hat{W}_{ic}$ are estimated critic weights of the optimal weights and $U_i := [e_i^T u_i^T u_{\mathcal{N}_i}^T v_i^T v_{\mathcal{N}_i}^T]^T$; the control actor approximator is given as

$$\hat{u}_i(e_i) = \hat{W}_{ia}^T e_i, \forall i \in \mathcal{N},$$

where $\hat{W}_{ia} \in \mathbb{R}^{n \times m_i}$ are estimated actor weights of the optimal weights; and the adversarial actor approximator is given by,

$$\hat{v}_i(e_i) = \hat{W}_{id}^T e_i, \forall i \in \mathcal{N},$$

where $\hat{W}_{id} \in \mathbb{R}^{n \times l_i}$ are estimated actor weights of the optimal weights.

The tuning laws for the critic and the actor can be found by using gradient descent as in the Optimal Regulation part.

Algorithm 3 gives the pseudocode for the approach.

Algorithm 3 Multi-agent Q-learning

-
- 1: **procedure**
 - 2: Start with initial conditions for every agent $x_i(0)$, and random initial weights $\hat{W}_{ic}(0)$, $\hat{W}_{ia}(0)$, $\hat{W}_{id}(0)$, for the critic, actor, and worst-case adversarial approximator for each agent.
 - 3: Propagate t , $x_i(t)$, and $x_j(t)$ in the neighborhood to compute e_i .
 - 4: Propagate $\hat{W}_{ic}(t)$, $\hat{W}_{ia}(t)$, $\hat{W}_{id}(t)$.
 - 5: Compute the Q-function $\hat{Q}_i$, the control $\hat{u}_i$, and the adversarial input $\hat{v}_i$ for each agent.
 - 6: **end procedure**
-

More details about multi-agent model-free learning can be found in Vamvoudakis and Hespanha (2018), Vamvoudakis (2017a), and Yang et al. (2018b).

Networked Systems with Intermittent/Hybrid Feedback

In conventional implementations of control systems, control tasks are usually executed by periodically sampling the plant's output and updating the control inputs. Selection of sampling period is traditionally performed during the control design stage, having in mind the trade-off between the reconstruction of the continuous-time signal and the load on the computer (Heemels et al. 2012). In many applications, however, conventional design methods may not represent an efficient solution. In network control systems (NCS) where communication channels are shared with multiple and possibly remotely located sensors, actuators, and controllers (Hespanha et al. 2007), periodic sampling, computation, and transmission of data could result in inefficient use of resources of bandwidth and energy. We show a new model-free event-triggered optimal control algorithm for continuous-time linear systems. In order to provide a model-free solution, we adopt a Q-learning framework with a critic network to approximate the optimal cost and a zero-order hold actor network to approximate the optimal control.

Consider the system described by (1). In order to save resources, the controller will work with a sampled version of the state. For that reason, one needs to introduce a *sampled-data component*

that is characterized by a monotone increasing sequence of sampling instants (broadcast release times) $\{r_j\}_{j=0}^{\infty}$, where r_j is the j -th consecutive sampling instant (impulse times) that satisfies $0 \leq t_0 < t_1 < \dots < r_j < \dots$ and $\lim_{j \rightarrow \infty} r_j = \infty$. The output of the *sampled-data component* is a sequence of sampled states $\hat{x}$ with $\hat{x} = x(r_j)$ for all $t \in (r_j, r_{j+1}]$ and $j \in \mathbb{N}$. The controller maps the sampled state onto a control vector u , which after using a zero-order hold (ZOH) becomes a continuous-time input signal. For simplicity we will assume that the sampled-data system has zero task delays.

In order to decide when to trigger an event, we will define the gap between the current state $x(t)$ and the sampled state $\hat{x}(t)$ as, $e(t) := \hat{x}(t) - x(t)$, where,

$$\hat{x}(t) = \begin{cases} x(r_j), & \forall t \in (r_j, r_{j+1}] \\ x(t), & t = r_j. \end{cases}$$

The ultimate goal is to find a value function with a quantified guaranteed performance that is ϵ -close to the time-triggered optimal value function V^* (value with infinite controller bandwidth) as defined in (2) and without any information of the system matrices of (1).

In order to reduce the communication between the controller and the plant, one needs to use an event-triggered version of the Riccati equation by introducing a *sampled-data component* with aperiodic controller updates that ensure a certain condition on the state of the plant to guarantee stability and performance as we will see in the subsequent analysis. For that reason, the control input uses the sampled-state information instead of the true one to write,

$$u_d^*(\hat{x}) = -R^{-1}B^T P_d \hat{x}, \quad \forall \hat{x},$$

where with $P_d \in \mathbb{R}^{n \times n}$ a unique symmetric positive matrix. Note that as the bandwidth approaches infinity, one has $V^*(\hat{x}) \rightarrow V^*(x)$.

Model-Free Formulation

The Q-function is given as in (3), but instead of u , we shall use u_d that uses the sampled-state information instead of the true one.

In contrast to existing event-triggered designs, where complete knowledge of the system dynamics is required, the aforementioned method is able to obviate this requirement by using the intermittent Q-learning algorithm. The actor-critic approximator structure is employed to co-design the event-triggering condition and controller. The combined closed-loop system can be written as an impulsive system, which is proved to have an asymptotically stable equilibrium point without any Zeno behavior. A qualitative performance analysis of the Q-learning is given in comparison to the continuous optimal feedback and the degree of sub-optimality is established.

The update for the critic is the same as the one for the Q-function given in (3), but the actor follows an impulsive update of the form,

$$\begin{cases} \dot{\hat{W}}_a = 0, & \forall t \in (r_j, r_{j+1}] \\ \hat{W}_a^+ = \hat{W}_a - \alpha_a \frac{1}{(1+x(t)^T x(t))} \frac{\partial K_2}{\partial \hat{W}_a} \\ \quad = \hat{W}_a - \alpha_a \frac{x(t)}{(1+x(t)^T x(t))} e_a^T, & t = r_j \end{cases}$$

where $\alpha_a \in \mathbb{R}^+$ is a constant gain that determines the speed of convergence.

Algorithm 4 gives the pseudocode for the approach.

Algorithm 4 Intermittent Q-learning for networked control

- 1: **procedure**
 - 2: Start with initial conditions $x(0)$, $\hat{x}(0)$, and random initial weights $\hat{W}_c(0)$, $\hat{W}_a(0)$, for the critic and the actor.
 - 3: Propagate t , $x(t)$, $\hat{x}(t)$, $\forall t \in (r_j, r_{j+1}]$.

More details about model-based and model-free intermittent RL algorithms are given in Vamvoudakis (2014), Vamvoudakis and Ferraz (2018), Yang et al. (2019), Yang et al. (2018a), and Vamvoudakis and Ferraz (2016).

Optimal Tracking with Intermittent Feedback

We have extended the work presented before, to consider event-triggered optimal tracking. In order to do that, we have augmented the system and the reference dynamics to convert the tracking problem into a regulator one by appropriately choosing the discount factor and the weighting of the tracking error in the performance. For more details, see Vamvoudakis et al. (2017a) and Vamvoudakis (2016).

Summary and Future Directions

The use of Q-learning to solve model-free optimization-based control problems is an area that has attracted a significant amount of research attention in recent years and will continue to grow as autonomy becomes a necessity. The developed methods implicitly solve the required design equations without ever explicitly solving them. Different aspects of the control inputs (decision-makers) in terms of cooperation, altruistic vs. selfish behavior, and intermittent feedback, are explored.

The integration of Q-learning with control methods could advance the human-agent feedback loops while optimizing performance and advancing data decision models. Note that all the aforementioned algorithms use full-state feedback. An interesting direction to pursue would be to extend the approaches to robot motion planning that combine game theory, formal control synthesis, and learning. Finally, existing Q-learning techniques for large-scale dynamic systems require spending a long time to gather large amount of data for learning an optimal solution. Moreover, availability of large amounts of data requires novel decision and control schemes that

focus selectively on the data that are relevant for the current situation and ignore relatively unimportant details. The demands for fast response based on available information in a large-scale system impose new requirements for fast and efficient decision. The future work is to design new classes of learning-based controllers that lead to satisfactory and good enough solutions that deliver prescribed aspiration levels of satisfactory for large-scale systems that require making fast and skillful decisions in highly constrained, uncertain, and adversary environments with overload information.

KS, USA

Abstract

Hybrid systems combine continuous and discrete inputs, outputs, states, and dynamics. Models of hybrid systems combine models of continuous dynamics, such as differential equations, with models of discrete dynamics, such as finite automata. These rich entities can be used to model a wide variety of real-world phenomena. Hybrid models can be viewed as being built up from constituent continuous models with discrete phenomena added or vice versa.

Keywords

Hybrid dynamical systems · Hybrid automata · Cyber-physical systems · Embedded control · Networked control systems · Differential equations · Finite automata

Introduction

Hybrid systems arise in physical systems that make and break contacts (e.g., a bouncing ball) or when there is a logical switching among dynamics (e.g., shifting gears in a car). They arise

whenever one uses computations or finite-state logic to govern continuous physical processes (as in embedded control or cyber-physical systems) or from topological and network constraints interacting with continuous control (as in networked control systems).

Hybrid systems can be used to model systems with relays, switches, and hysteresis (Tavernini 1987), computer disk drives (Gollu and Varaiya 1989), transmissions and stepper motors (Brockett 1993), constrained robotic systems (Back et al. 1993), flight controllers and air traffic management systems (Meyer 1994; Tomlin et al. 1998), multi-vehicle formations and coordination (Tabuada et al. 2001), analog/digital circuits (Maler and Yovine 1996), and biological applications (Ghosh and Tomlin 2004).

In the case of a hybrid *control* system, models contain both continuous and discrete inputs, and outputs plus internal components themselves may be hybrid; see Fig. 1. There, I and O are discrete (countable) sets of symbols and U and Y are continua.

As an example, consider a flight control system organized around the *modes* Take-Off, Ascend, Cruise, Descend, and Land. A hybrid controller would orchestrate flight among these different regimes, producing flight paths considering air traffic, weather, fuel economy, and passenger comfort.

The rest of this entry provides a reference to the mathematical modeling of hybrid systems, including how they may be built up, step by step, by adding discrete phenomena to continuous dynamical models and by adding continuous phenomena to discrete models. The most commonly used continuous dynamical models are ordinary differential equations (ODEs); the most common discrete models are finite automata.

From Continuous Toward Hybrid

In this section, we start with ordinary differential equations (ODEs) as a base continuous model and then add various discrete phenomenon to them, working toward more and more expressive “hybrid dynamical systems” models. One can

Modeling Hybrid Systems, Fig. 1 Block diagram of a hybrid control system

also use difference equations as the base continuous model (Branicky 1995).

Base Continuous Model: ODEs

Consider a continuous dynamical system defined by *ordinary differential equations (ODEs)*:

$$\dot{x}(t) = f(x(t)), \quad (1)$$

where $x(t) \in X \subset \mathbf{R}^n$. The function $f: X \rightarrow \mathbf{R}^n$ is called a *vector field* on $\mathbf{R}^n$. We assume existence and uniqueness of solutions; see Hirsch and Smale (1974) for conditions.

The system of ODEs in Eq. (1) is called *autonomous* or *time-invariant* because its vector field does not depend explicitly on time. If it did depend explicitly on time, it would be *nonautonomous* or *time-varying*, denoted as follows:

$$\dot{x}(t) = f(x(t), t), \quad (2)$$

An ODE with inputs and outputs (Luenberger 1979; Sontag 1990) is given by

$$\begin{aligned} \dot{x}(t) &= f(x(t), u(t)), \\ y(t) &= h(x(t), u(t)), \end{aligned} \quad (3)$$

where $x(t) \in X \subset \mathbf{R}^n$, $u(t) \in U \subset \mathbf{R}^m$, $y \in Y \subset \mathbf{R}^p$, $f: \mathbf{R}^n \times \mathbf{R}^m \rightarrow \mathbf{R}^n$, and $h: \mathbf{R}^n \rightarrow \mathbf{R}^p$. The functions $u(\cdot)$ and $y(\cdot)$ are the *inputs* and *outputs*, respectively. When inputs are present as in Eq. (3), we say $f(\cdot)$ is a *controlled vector field*.

Differential Inclusions

A *differential inclusion* permits the derivative to belong to a set and is written as:

$$\dot{x}(t) \in F(x(t)),$$

where $F(x(t))$ is a set of vectors in $\mathbf{R}^n$. A differential inclusion can model nondeterminism, including that arising from modeling uncertainty, disturbances, or controls. For example, the controlled differential equation of Eq. (3) can be viewed as an inclusion by setting $F(x) = \bigcup_{u \in U} f(x, u)$.

A *rectangular inclusion* admits derivatives in an interval. For example, an inexact clock with a time-varying rate between 0.9 and 1.1 can be modeled by the rectangular inclusion $\dot{x} \in [0.9, 1.1]$.

Adding Discrete Phenomena

In this section, we discuss the discrete phenomena that arise in hybrid systems:

1. autonomous switching, where the vector field changes discontinuously;
2. autonomous jumps, where the state changes discontinuously;
3. controlled switching, where a control switches vector fields discontinuously;
4. controlled jumps, where a control changes a state discontinuously.

Autonomous Switching

Autonomous switching is the phenomenon where the vector field $f(\cdot)$ changes discontinuously when the continuous state $x(\cdot)$ hits certain “boundaries” (Antsaklis et al. 1993; Nerode and Kohn 1993; Tavernini 1987; Witsenhausen 1966).

Example 1 (Thermostat) The temperature dynamics of a furnace may be quite complicated, depending on outside temperature and humidity; insulation and layout; whether doors are closed, vents are open, or people are present; etc. We abstract its behavior to two modes. When the furnace is **On**, the dynamics are $\dot{x}(t) = f_1(x(t))$, where $x(t)$ is the temperature at time t ; when the furnace is **Off**, the dynamics are governed by $\dot{x}(t) = f_0(x(t))$. This results in a *switched system*:

$$\dot{x}(t) = f_{q(t)}(x(t)),$$

where $q(t) = 0$ or 1 depending on whether the furnace is **Off** or **On**, resp.

A particularly rich class of hybrid systems are *switched linear systems*:

$$\dot{x}(t) = A_{q(t)}x(t), \quad q \in \{1, \dots, N\},$$

where $x(t) \in \mathbf{R}^n$ and each $A_q \in \mathbf{R}^{n \times n}$. Such a system is autonomous if the switching is a function of $x(t)$. The “switching rules” may interact with the constituent dynamics to produce unexpected results, such as instability arising from switching between stable linear systems (Branicky 1998).

Autonomous Jumps

An *autonomous jump* or *autonomous impulse* occurs when the continuous state $x(\cdot)$ jumps discontinuously on hitting prescribed regions of the state space (Back et al. 1993; Bainov and Simeonov 1989). Simple examples of this phenomenon are systems involving collisions.

Example 2 (Bouncing Ball) Consider the vertical position and velocity of a ball of mass m under gravity:

$$\begin{aligned} \dot{x} &= v, \\ \dot{v} &= -mg. \end{aligned}$$

Upon hitting the ground (assuming downward velocity), we instantly set v to $-\rho v$, where $\rho \in [0, 1]$ is the coefficient of restitution. The jump in velocity can be encoded as a rule:

$$\text{“If at time } t, x(t) = 0 \text{ and } v(t) < 0, \text{ then } v(t^+) = -\rho v(t).”$$

In this case, $v(\cdot)$ is piecewise continuous (from the right), with discontinuities occurring when $x = 0$. This “rule” notation is general but cumbersome. It can be replaced with the following notation:

$$v^+(t) = -\rho v(t), \quad (x(t), v(t)) \in \{(0, v) \mid v < 0\}.$$

The equation uses the discrete-time transition notation of Sontag (1990) to denote the “successor” of $x(t)$.

More generally, a system with autonomous impulses may be written as:

$$\begin{aligned} \dot{z}(t) &= f(z(t)), & z(t) &\notin A, \\ z^+(t) &= G(z(t)), & z(t) &\in A. \end{aligned} \quad (4)$$

This system evolves according to the differential equation while z is in the complement of the *autonomous jump set* A ; the state is immediately reset according to the map G when z hits the set A .

Controlled Switching

Controlled switching is the phenomenon where the vector field $f(\cdot)$ changes abruptly in response to a control input. This can be interpreted as switching between different vector fields (Zabczyk 1973). Controlled switching arises when one is allowed to pick among a number of vector fields:

$$\dot{x} = f_q(x), \quad q \in Q \simeq \{1, 2, \dots, N\}.$$

Here, the discrete state q that is active at any given time is chosen by the controller.

Example 3 (Transmission) Consider a simplified model of a manual transmission (Brockett 1993):

$$\begin{aligned} \dot{x}_1 &= x_2, \\ \dot{x}_2 &= [-a(x_2/v) + u]/(1 + v), \end{aligned}$$

where x_1 is the ground speed, x_2 is the engine RPM, $u \in [0, 1]$ is the throttle position, and $v \in \{1, 2, 3, 4\}$ is the gear shift position. The function a is positive for positive argument.

Controlled Jumps

A *controlled jump* or *controlled impulse* is the phenomenon where the continuous state $x(\cdot)$ changes discontinuously in response to a control input.

Example 4 (Inventory Management) In a simple inventory management model (Bensoussan and Lions 1984), there are a “discrete” set of restocking times $\theta_1 < \theta_2 < \dots$ and associated order amounts $\alpha_1, \alpha_2, \dots$. The equations governing the

stock at any given moment are:

$$\dot{x}(t) = -\mu(t) + \sum_i \delta(t - \theta_i) \alpha_i,$$

where μ represents continuous degradation or utilization and δ is the Dirac delta.

From Discrete Toward Hybrid

In this section, we start with finite automata as a base discrete model. We then successively add time and continuous dynamics to them, working toward more and more expressive “hybrid automata” models.

Base Discrete Model: Finite Automata

An *input-less automaton* is a dynamical system with a discrete state space:

$$q_{k+1} = v(q_k),$$

where $q_k \in Q$, a finite set.

Augmenting with finite inputs, we arrive at a (*deterministic*) *finite automaton (DFA)* which is a four-tuple $\mathcal{A} = (Q, I, v, q_0)$, where Q is a finite set of *states*; I is a finite set of symbols (known as an *alphabet*), called the *input alphabet*; v is the *transition function* mapping $Q \times I$ into Q ; and $q_0 \in Q$ is the *initial state*.

A DFA begins in state q_0 and then responds to sequences of input symbols (known as *strings* or *words*) over I . In one move, a DFA in state q receives symbol $a \in I$ and enters state $v(q, a)$. On input word $w = a_1 a_2 \cdots a_n$, the DFA in state r_0 successively receives symbols and sequences through states $r_1, r_2, \dots, r_n$, such that

$$r_{k+1} = v(r_k, a_{k+1}); \quad k = 0, 1, 2, \dots, n-1. \quad (5)$$

This sequence of states is a *run* of the DFA over w .

A *nondeterministic finite automaton (NFA)* allows a *set* of start states and a set-valued transition function mapping $Q \times I$ into 2^Q , so that at any stage, the automaton may be in a set of states consistent with its transition function and

the symbols seen so far. In one move, an NFA in state q receives symbol a and nondeterministically enters any one of the states in $v(q, a)$. On input word $w = a_1 a_2 \cdots a_n$, an NFA in state r_0 nondeterministically sequences through states $r_1, r_2, \dots, r_n$ such that

$$r_{k+1} \in v(r_k, a_{k+1}); \quad k = 0, 1, 2, \dots, n-1.$$

Again, we call this sequence a *run* of the NFA over w . In general, NFAs have many runs associated with each string; a DFA only has one.

General Automata

DFAs and NFAs can be augmented with marked states (Hopcroft and Ullman 1979) or process infinite length strings of symbols, known as ω -strings (read “omega strings”) or ω -words over an alphabet I . They can also allow outputs, as in Mealy and Moore machines (Hopcroft and Ullman 1979). Finally, allowing a countable number of states covers models such as pushdown automata and Turing machines (Hopcroft and Ullman 1979) and Petri nets (Cassandras and Lafortune 1999).

A model encompassing these is a *discrete automaton*, which is a five-tuple (Q, I, v, O, η) , consisting of the state space, input alphabet, transition function, output alphabet, and output function, respectively. We assume that Q , I , and O are each countable. When these sets are finite, the result is a finite automaton with output. In any case, the functions involved are $v : Q \times I \rightarrow Q$ and $\eta : Q \times I \rightarrow O$. The *dynamics* of the automaton are specified by

$$\begin{aligned} q_{k+1} &= v(q_k, i_k), \\ o_k &= \eta(q_k, i_k). \end{aligned} \quad (6)$$

Adding Continuous Phenomena

To move toward hybrid systems, we add successively more complex continuous phenomena to finite and discrete automata:

1. *Global Time*, where one adds a single global clock with unit rate.
2. *Timed Automata*, where one adds a set of unit-rate clocks and the ability to reset them,

3. *Skewed-Clock Automata*, where each clock has a different, uniform (in each location), rational rate.
4. *Multi-Rate Automata*, where each clock variable may take on different, rational rates in each location.

For ease of discussion, note that discrete states are also referred to as *modes*, *phases*, or *locations*.

Global Time

Normally, discrete automata are thought of as evolving in “abstract time,” where only the ordering of symbols or “events” matters. See Eq. (6). We may add the notion of time by associating with the k th transition the time, t_k , at which it occurs (Cassandras and Lafortune 1999):

$$\begin{aligned} q(t_{k+1}) &= v(q(t_k), i(t_k)), \\ o(t_k) &= \eta(q(t_k), i(t_k)). \end{aligned}$$

This automaton may be thought of as operating in “continuous time,” where the state, input, and output symbols are piecewise continuous functions. Again, using the transition notation of Sontag (1990), we obtain:

$$\begin{aligned} q^+(t) &= v(q(t), i(t)), \\ o(t) &= \eta(q(t), i(t)). \end{aligned} \quad (7)$$

Here, the state q and output o are piecewise continuous functions that only change when the input symbol $i(t)$ changes.

Timed Automata

Timed automata (Alur and Dill 1994) process *timed* words. A *timed word* (over input alphabet I) is a finite sequence of symbols and their respective times of occurrence: $(i_1, t_1), (i_2, t_2), \dots, (i_N, t_N)$, where each $i_k \in I$, each $t_k \in \mathbf{R}_+$, and times *strictly increase*: $t_{k+1} > t_k$. A *timed ω -word*, $(i_1, t_1), (i_2, t_2), \dots$, adds the constraint that time *progresses* without bound: for all $T \in \mathbf{R}_+$, there exists a k such that $t_k > T$. The latter condition is necessary to avoid so-called *Zeno behavior*. For example, the sequence

of times $1/2, 3/4, 7/8, 15/16, 31/32, \dots$ is not a valid time sequence.

A *timed automaton* is a DFA plus a finite number of real-valued clocks, and the ability to reset clocks and test constraints on clocks when traversing edges. Each *clock constraint*, χ , may take one of the forms:

$$(x \leq c), \quad (c \leq x), \quad \neg\chi_0, \quad \chi_1 \wedge \chi_2,$$

where x is a clock variable, c is a rational constant, $\neg$ denotes logical negation, $\wedge$ denotes logical “and,” and χ_i are themselves valid clock constraints. These primitives plus the rules of logic allow one to build up more complicated tests, including $(x = c)$, $(x < c)$, $\chi_1 \vee \chi_2$, and **True**.

In drawings of timed automata, the notation $? \chi$ is used to denote the fact that the edge *may* be taken only if the clock constraint χ is true. We have found it useful to also add $! \chi$, meaning that the edge *must* be taken when χ is true.

Many decision and verification problems for timed automata may be translated directly into questions about (generally much larger) finite-state automata (Alur and Dill 1994).

Skewed-Clock Automata

Summarizing, a timed automaton has a finite set, C , of clocks, $x_i \in C$ such that $\dot{x}_i = 1$ for all clocks and all locations. A *skewed-clock automaton* allows $\dot{x}_i = k_i$ where each k_i is a rational number.

Remark 1 Skewed-clock automata are equivalent to timed automata. That is, any skewed-clock automaton can be converted into an equivalent timed automaton and vice versa (by replacing clock i with a unit-rate clock and dividing any constant to which x_i is compared by k_i).

Multi-rate Automata

A *multi-rate automaton* allows $\dot{x}_i = k_{i,q}$ at location $q \in Q$, where each $k_{i,q}$ is a rational number; see Fig. 2. Note that for multi-rate automata:

- Some variables might have the same rates in all states, e.g., w in Fig. 2.

- Some variables might be *stopwatches* (derivative either 0 or 1) measuring a particular time. E.g., x in Fig. 2 is a stopwatch measuring the elapsed time spent in the upper left state.
- Not all dynamics change at every transition. E.g., y in Fig. 2 changes dynamics in transitioning along Edges 2 and 3 but not along Edge 1.
- Every skewed-clock automaton is a multi-rate automaton that simply has $k_{i,q} = k_i$ for all $q \in Q$.

Multi-rate automata may exhibit *Zeno behavior* (Zhang et al. 2000). Their behavior may even be computationally undecidable (Henzinger et al. 1998). However, a simple constraint on multi-rate automata yields a class that permits analysis: *initialized* multi-rate automata add the constraint that a variable must be reset when traversing an edge if its dynamics changes while crossing that edge. This would be the case for the automaton in Fig. 2 if x and z were initialized on Edge 1, y and z were initialized on Edge 2, and x , y , and z were initialized on Edge 3.

Remark 2 An initialized multi-rate automaton can be converted into a timed automaton (Henzinger et al. 1998).

Other Refinements

Rectangular Automata

Progressing from rates to rectangular inclusions permits rectangular and multi-rectangular automata. A *rectangular automaton* has each $\dot{x}_i \in [l_i, u_i]$, where l_i and u_i are rational constants, uniformly over all locations. Therefore, they generalize skewed-clock automata. Indeed, setting $l_i = u_i = k_i$ recovers them. Similarly, multi-rate automata can be generalized to *multi-rectangular automata*. Here, each variable satisfies a (generally different) rectangular inclusion in each location. Rectangular automata also allow the setting of initial values and the resetting of variables to be performed within rectangles. *Initialized* multi-rectangular automata must reset a variable along any edge that changes the rectangular inclusion governing its dynamics.

Remark 3 An initialized multi-rectangular automaton can be converted to an initialized multi-rate automaton and hence a timed automaton (Henzinger et al. 1998).

Adding Control

A rich control theory for general automata models can be built by allowing the disabling of certain *controllable* input symbols. See Ramadge and Wonham (1989) and Cassandras and Lafor-
tune (1999).

Modeling Hybrid Systems, Fig. 2 Example multi-rate automaton (edge data suppressed)

Hybrid Dynamical Systems and Hybrid Automata

A hybrid dynamical system is an indexed collection of ODEs along with maps for “jumping” among them (switching dynamical system and/or resetting the state). The jumping occurs whenever the state satisfies certain conditions, given by its membership in a specified subset of the state space. The entire system can be thought of as a sequential patching together of ODEs with initial and final states, with jumps performing a reset to a (generally different) initial state of a (generally different) ODE whenever a final state is reached; see Fig. 3.

More formally, a *hybrid dynamical system* (HDS) is a four-tuple $H = (Q, \Sigma, A, G)$:

- Q is a countable set of *index* or *discrete states*.
- $\Sigma = \{\Sigma_q\}_{q \in Q}$ is a collection of *systems* of ODEs. Thus, each system Σ_q has vector fields $f_q : X_q \rightarrow \mathbf{R}^{d_q}$, representing *continuous dynamics*, evolving on $X_q \subset \mathbf{R}^{d_q}$, $d_q \in \mathbf{Z}_+$, which are *continuous state spaces*.
- $A = \{A_q\}_{q \in Q}$, $A_q \subset X_q$ for each $q \in Q$, is a collection of *autonomous jump sets*.

- $G = \{G_q\}_{q \in Q}$, where $G_q : A_q \rightarrow S$, are *autonomous jump transition maps* that represent the *discrete dynamics*.

Thus, $S = \bigcup_{q \in Q} X_q \times \{q\}$ is the *hybrid state space* of H . For convenience, the following shorthand is used: $S_q = X_q \times \{q\}$, and $A = \bigcup_{q \in Q} A_q \times \{q\}$ is the *autonomous jump set*; $G : A \rightarrow S$ is the *autonomous jump transition map*, constructed component-wise. The *jump destination sets* $D = \{D_q\}_{q \in Q}$ are defined by $D_q = \pi_1[G(A) \cap S_q]$, where π_i is projection onto the i th coordinate. The *switching manifolds* or *transition manifolds*, $M_{q,p} \subset A_q$, are given by $M_{q,p} = G_q^{-1}(D_p, p)$, i.e., the set of states for which transitions from index q to index p can occur.

The dynamics of HDS H are as follows. The system starts in some hybrid state in $S \setminus A$, say $s_0 = (x_0, q_0)$. It evolves according to $\dot{x} = f_{q_0}(x)$ until the state enters – if ever – A_{q_0} at the point $s_1^- = (x_1^-, q_0)$. At this time, it is instantly transferred according to the transition map to $G_{q_0}(x_1^-) = (x_1, q_1) \equiv s_1$, from which the process continues.

M

Modeling Hybrid Systems, Fig. 3 Hybrid dynamical system

We now collect some notes about HDS:

- *ODEs and automata.* In the case $|Q| = 1$ and $A = \emptyset$, we recover all differential equations. With $|Q| = N$ and each $f_q \equiv 0$, we recover finite automata.
- *Outputs.* It is straightforward to add continuous and discrete output maps for each constituent system.
- *Changing state space and overlaps.* The state space and its dimension may change, which is useful in modeling component failures or changes in dynamical description based on autonomous – or later, controlled – events which change it. Examples include inelastic collisions or aircraft mode transitions that change the variables to be controlled (Meyer 1994). The model allows the X_q to overlap and the inclusion of multiple copies of the same space. This can be used to model overlapping local coordinate systems (Back et al. 1993) or hysteresis (Branicky 1995).
- *Transition Delays.* One can model situations where the autonomous jumps are not instantaneous by adding an *autonomous jump delay map*, $\Delta_a : A \times V \rightarrow \mathbf{R}_+$. Such a map associates a (possibly zero) delay to each autonomous jump. Thus, a jump begins at some time, τ , and is completed at some later time $\Gamma \geq \tau$. This concept is useful as jumps may be introduced to represent an aggregate set of (relatively) fast, transitory dynamics. Also, some commands may have a finite delay from issuance to completion, for example, closing a hydraulic valve.
- *Well-Defined Solutions.* For the solutions described to be well-defined, it is sufficient that for all q , A_q is closed, $D_q \cap A_q = \emptyset$, and f_q is Lipschitz continuous. Note, however, that in general these solutions are not continuous in the initial conditions. See Branicky (1995) for details.
- *Generalizations.* A more general notion, *GHDS* (*General HDS*), is due to Branicky (1995). It allows each ODE to be replaced by a general dynamical system. Most notably one could replace the ODEs with difference equations.

HDS with $|Q|$ finite are a coupling of finite automata and differential equations. Indeed, an HDS can be pictured as a *hybrid automaton* as in Fig. 4. Therein, each node is a constituent ODE, with the index the name of the node. Each edge represents a possible transition between constituent systems, labeled by the appropriate condition for the transition's being “enabled” and the update of the continuous state; cf. Harel (1987). The notation $![\text{condition}]$ denotes that the transition *must* be taken when enabled.

Example 5 (Bouncing Ball Revisited) The hybrid automaton associated with the bouncing ball of Example 2 appears in Fig. 5. The velocity resets are autonomous and hence must occur when the ball hits the ground.

Example 6 (HVAC Revisited) Reconsider the furnace controller of Example 1, adding the goal of keeping the temperature about 23 degrees Celsius. To avoid inordinate switching around the

Modeling Hybrid Systems, Fig. 4 Hybrid automaton representation of an HDS

Modeling Hybrid Systems, Fig. 5 Hybrid automaton for bouncing ball of Example 2

Modeling Hybrid Systems, Fig. 6 Hybrid control systems for a furnace: (l) prototypical hysteresis, (r) adding timing constraints

set point (known as *chattering*), we implement a control with hysteresis as in Fig. 6(l). This controller will (1) turn the furnace **On** when it is **Off** and the temperature falls below 21 and (2) turn the furnace **Off** when it is **On** and the temperature rises above 25. Suppose, in addition, that the furnace should never be on more than 55 min straight and must remain **Off** for at least 5 min. These objectives can be accomplished by adding a timer variable that is reset on state transitions; see Fig. 6(r).

Adding Control

One may add the ability to control an HDS by choosing among sets of possible actions at various times. Specifically, we allow (1) the possibility of continuous controls for each ODE, (2) the ability to make decisions at autonomous jump points, and (3) the ability to make controlled jumps, where one may decide to jump or not and have a choice of destination when the state satisfies certain constraints.

Formally, a *controlled hybrid dynamical system* (CHDS) is a six-tuple $H_c = (Q, \Sigma, A, G, C, F)$:

- $\Sigma = \{\Sigma_q\}_{q \in Q}$ is now a collection of *controlled* ODEs, with controlled vector fields $f_q : X_q \times U_q \rightarrow \mathbf{R}^{d_q}$ representing (controlled) *continuous dynamics*, where $U_q \subset \mathbf{R}^{m_q}$ and $m_q \in \mathbf{Z}_+$ are *continuous control spaces*.

- $G = \{G_q\}_{q \in Q}$, where $G_q : A_q \times V_q \rightarrow S$ are *autonomous jump transition maps*, now modulated by *discrete decision sets* V_q .
- $C = \{C_q\}_{q \in Q}$, $C_q \subset X_q$, is a collection of *controlled jump sets*.
- $F = \{F_q\}_{q \in Q}$, where $F_q : C_q \rightarrow 2^S$, is a collection of set-valued *controlled jump destination maps*.

Again, $S = \bigcup_{q \in Q} X_q \times \{q\}$ is the hybrid state space of H_c . As before, we use some shorthand beyond that defined for HDS above. We let $C = \bigcup_{q \in Q} C_q \times \{q\}$; we let $F : C \rightarrow 2^S$ denote the set-valued map composed in the obvious way from the set-valued maps F_q . Let $\tilde{G}_q = \{G(x, v) | v \in V_q\}$

The dynamics of the CHDS H_c are as follows. The system is assumed to start in some hybrid state in $S \setminus A$, say $s_0 = (x_0, q_0)$. It evolves according to $\dot{x} = f_{q_0}(x, u)$ until the state enters – if ever – either A_{q_0} or C_{q_0} at the point $s_1^- = (x_1^-, q_0)$. If it enters A_{q_0} , then it *must* be transferred according to transition map $G_{q_0}(x_1^-, v)$ for some chosen $v \in V_{q_0}$. If it enters C_{q_0} , then we *may* choose to jump, and, if so, we may choose the destination to be any point in $F_{q_0}(x_1^-)$. In either case, we arrive at a point $s_1 = (x_1, q_1)$ from which the process continues; see Fig. 7.

A CHDS can also be pictured as an automaton, as in Fig. 8. There, each node is a constituent controlled ODE, with the index the name of the node. Again, the notation $?[\text{condition}]$ denotes

Modeling Hybrid Systems, Fig. 7
Controlled hybrid dynamical system

Modeling Hybrid Systems, Fig. 8 Hybrid automaton representation of a CHDS

an enabled transition that *may* be taken on command; “ $\in$ ” means reassignment to some value in the given set.

Example 7 (Transmission Revisited) Some modern performance sedans offer the driver the ability to shift gears electronically. However, there are often rules in place that prevent certain shifts, or automatically perform certain shifts, to maintain safe operation and reduce wear. These rules are often a function of the engine RPM (x_2 in Example 3). A portion of a hybrid controller incorporating such logic is shown in Fig. 9. The rules pictured only allow the driver to shift from

Gear 1 to Gear 2 if RPM exceeds 1800 but automatically makes this switch if RPM exceeds 3500. Similar rules would exist for higher gears; more complicated rules might exist regarding **Neutral** and **Reverse**.

Summary and Future Directions

This entry summarized quite general models for hybrid systems, namely, hybrid dynamical systems and hybrid automata. It built these up successively from base models of completely

Modeling Hybrid Systems, Fig. 9 Portion of a hybrid control system for the transmission of Example 3

continuous and completely discrete models: ODEs and finite automata. Future directions largely revolve around using these to model new applications, such as autonomous cars and drones. Another direction involves identifying classes that are amenable to (automated) design, analysis, and verification.

Modeling of Dynamic Systems from First Principles

S. Torkel Glad

Department of Electrical Engineering,
Linköping University, Linköping, Sweden

Abstract

This paper describes how models can be formed from the basic principles of physics and the other fields of science. Use can be made of similarities between different domains which leads to the concepts of bond graphs and, more abstractly, to port-controlled Hamiltonian systems. The class of models is naturally extended to differential algebraic equations (DAE) models. The concepts described here form a natural basis for parameter identification in gray box models.

Keywords

Physical modeling · Grey box model · DAE

Introduction

The approach to the modeling of dynamic systems depends on how much is known about the system. When the internal mechanisms are known, it is natural to model them using known relationships from physics, chemistry, biology, etc. Often the result is a model of the following form

$$\frac{dx}{dt} = f(x, u; \theta), \quad y = h(x, u; \theta) \quad (1)$$

where u is the input and y the output, and the state x contains internal physical variables, while θ contains parameters. Typically all of these are vectors. The model is known as a state-space model. In many cases some elements in θ are unknown and have to be determined using parameter estimation. When used in connection with system identification, these models are some-

times referred to as *gray box* models (in contrast to black box models) to indicate that some degree of physical knowledge is assumed.

Overview of Physical Modeling

Since modeling covers such a wide variety of physical systems, there are no universal systematic principles. However a few concepts have wide application. One of them is the preservation of certain quantities like energy, leading to *balance equations*. A simple example is given by the heating of a body. If W is the energy stored as heat, P_1 an external power input, and P_2 the heat loss to the environment per time unit, energy balance gives

$$\frac{dW}{dt} = P_1 - P_2 \quad (2)$$

To get a complete model, one needs also *constitutive relations*, i.e., relations between relevant physical variables. For instance, one might know that the stored energy is proportional to the temperature T , $W = CT$ and that the energy loss is from black body radiation, $P_2 = kT^4$. The model is then

$$C \frac{dT}{dt} = P_1 - kT^4 \quad (3)$$

The model is now an ordinary differential equation with state variable T , input variable P_1 , and parameters C and k .

Physical Analogies and General structures

Physical Analogies

Physicists and engineers have noted that modeling in different areas of physics often give very similar models. The term “analogies” is often used in modeling to describe this fact. Here we will show some analogies between electrical and mechanical phenomena. Consider the electric circuit given in Fig. 1. An ideal voltage source is connected in series with an inductor, a resistor, and a capacitor. Using u and v to denote the

voltages over the voltage source and capacitor, respectively, and i to denote the current, a mathematical model is

$$\begin{aligned} C \frac{dv}{dt} &= i \\ L \frac{di}{dt} + Ri + v &= u \end{aligned} \quad (4)$$

The first equation uses the definition of capacitance, and the second one uses Kirchhoff's voltage law. Compare this to the mechanical system of Fig. 2 where an external force F is applied to a mass m that is also connected to a damper b and a spring with spring constant k . If S is the elongation force of the spring and w the velocity of the mass, a system model is

$$\begin{aligned} \frac{dS}{dt} &= kw \\ m \frac{dw}{dt} + bw + S &= F \end{aligned} \quad (5)$$

Here the first equation uses the definition of spring constant, and the second one uses Newton's second law. The models are seen to be the same with the following correspondences between time varying quantities

$$u \leftrightarrow F, \quad i \leftrightarrow w, \quad v \leftrightarrow S \quad (6)$$

and between parameters

Modeling of Dynamic Systems from First Principles, Fig. 1 Electric circuit

Modeling of Dynamic Systems from First Principles, Fig. 2 Mechanical system

$$C \leftrightarrow 1/k, \quad L \leftrightarrow m, \quad R \leftrightarrow b \quad (7)$$

Note that the products (voltage) $\times$ (current) and (force) $\times$ (velocity) give the power.

Bond Graphs

The bond graph is a tool to do systematic modeling based on the analogies of the previous section. The basic element is the bond

formed by a half-arrow showing the direction of positive energy flow. Two variables are associated with the bond, the *effort* variable e and the *flow* variable f . The product ef of these variables gives the power. In the electric domain, e is voltage, and f is current. For mechanical systems e is force, while f is velocity. Bond graph theory has three basic components to describe storage and dissipation of energy. The relations

$$\alpha \frac{de}{dt} = f, \quad \beta \frac{df}{dt} = e, \quad \gamma f = e \quad (8)$$

are known as C, I, and R elements, respectively. Input signals are modeled by elements called effort sources S_e or flow sources S_f , respectively. A bond graph describes the energy flow between these elements. When the energy flow is split, it can either be at s junctions where the flows are equal and the efforts are added or at a p junction where efforts are equal and flows are additive. The model (5), for instance, can be described by the bond graph in Fig. 3. The graph shows how the energy from the external force is split into the acceleration of the mass, the elongation of the spring, and dissipation into the damper. The splitting of the energy flow is accomplished by an s element, meaning that the velocity is the same for all elements but that the forces are added

$$F = N + S + T \quad (9)$$

From (8) it follows that

$$k^{-1} \frac{dS}{dt} = w, \quad m \frac{dw}{dt} = N, \quad bw = T \quad (10)$$

Modeling of Dynamic Systems from First Principles, Fig. 3 Bond graph for mechanical or electric system

Together (9) and (10) give the same model as (5). Using the correspondences (6) and (7), it is seen that the same bond graph can also represent the electric circuit (4). An overview of bond graph modeling is given in Rosenberg and Karnopp (1983). A general overview of modeling, including bond graphs and the connection with identification, can be found in Ljung and Glad (2016).

Port-Controlled Hamiltonian Systems

Another way of viewing the mechanical system would be to introduce x_1 as the length of the spring so that $dx_1/dt = w$. If H_1 is the energy stored in the spring, then the following relations hold.

$$H_1(x_1) = \frac{kx_1^2}{2}, \quad \frac{\partial H_1}{\partial x_1} = kx_1 = S \quad (11)$$

Introducing x_2 for the momentum and H_2 as the kinetic energy, one has $dx_2/dt = N$ and

$$H_2(x_2) = \frac{x_2^2}{2m}, \quad \frac{\partial H_2}{\partial x_2} = m^{-1}x_2 = w \quad (12)$$

Let $H = H_1 + H_2$ be the total energy. Then the following relation holds

$$\frac{dx}{dt} = \left(\begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} - \begin{bmatrix} 0 & 0 \\ 0 & b \end{bmatrix} \right) \begin{bmatrix} \partial H / \partial x_1 \\ \partial H / \partial x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} F \quad (13)$$

This model is a special case of

$$\frac{dx}{dt} = (M - R)\nabla H(x) + Bu \quad (14)$$

where M is a skew symmetric and R a nonnegative definite matrix, respectively. The model is a port-controlled Hamiltonian system with dissipation. Without external input ($B = 0$) and dissipation ($R = 0$), it reduces to an ordinary Hamiltonian system. For systems generated by simple bond graphs, it can be shown that the junction structure gives the skew symmetric M , while the R elements give the matrix R . The storage of energy in I and C elements is reflected in H . The reader is directed to Duindam et al. (2009) for a description of the port-Hamiltonian approach to modeling.

Component-Based Models and Modeling Languages

Since engineering systems are usually assembled from components, it is natural to treat their mathematical models in the same way. This is the idea behind block-oriented models where the output of one model is connected to the input of another one:

A nice feature of this block connection is that the state space description is preserved. Suppose the individual models are of the form (1)

$$\frac{dx_i}{dt} = f_i(x_i, u_i), \quad y_i = h_i(x_i, u_i), \quad i = 1, 2 \quad (15)$$

Then the connection $u_2 = y_1$ immediately gives the state space model

$$\frac{d}{dt} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} f_1(x_1, u_1) \\ f_2(x_2, h_1(x_1, u_1)) \end{bmatrix}, \quad y_2 = h_2(x_2, h_1(x_1, u_1)) \quad (16)$$

with input u_1 , output y_2 , and state (x_1, x_2) . This fact is the basis of block-oriented modeling and simulation tools like the MATLAB-based Simulink. Unfortunately the preservation of the state space structure does not extend to more general connections of systems. Consider, for instance, two pieces of rotating machinery described by

$$J_i \frac{d\omega_i}{dt} = -b_i \omega_i + M_i, \quad i = 1, 2 \quad (17)$$

where ω_i is the angular velocity, M_i the external torque, J_i the moment of inertia, and b_i the damping coefficient. Suppose the pieces are joined together so that they rotate with the same angular velocity. The mathematical model would then be

$$\begin{aligned} J_1 \frac{d\omega_1}{dt} &= -b_1 \omega_1 + M_1 \\ J_2 \frac{d\omega_2}{dt} &= -b_2 \omega_2 + M_2 \\ \omega_1 &= \omega_2 \\ M_1 &= -M_2 \end{aligned} \quad (18)$$

This is no longer a state space model of the form (1) but a mixture of dynamic and static relationships, usually referred to as a differential algebraic equation (DAE). The difference from the connection of blocks in block diagrams is that now the connection is not between an input and an output. Instead there are the equations $\omega_1 = \omega_2$ and $M_1 = -M_2$ that destroy the state space structure. There exist modeling languages like Modelica, Tiller (2012) and Fritzson (2015), or Simscape in MATLAB, MathWorks (2019) that accept this more general type of model. It is then possible to form model libraries of basic components that can be interconnected in very general ways to form models of complex systems. However this more general structure poses some challenges when it comes to analysis and simulation that are described in the next section.

Differential Algebraic Equations (DAE)

This model (18) is a special case of the general differential algebraic equation

$$F(dz/dt, z, u) = 0 \quad (19)$$

A good description of both theory and numerical properties of such equations is given in Kunkel and Mehrmann (2006). In many cases it is possible to split the variables and equations in such a way that the following structure is achieved.

$$F_1(dz_1/dt, z_1, z_2, u) = 0, \quad F_2(z_1, z_2, u) = 0 \quad (20)$$

If z_2 can be solved from the second equation and substituted into the first one and if dz_1/dt can then be solved from the first equation, the problem is reduced to an ordinary differential equation in z_1 . Often, however, the situation is not as simple as that. For the example (18), an addition of the first two equations gives

$$(J_1 + J_2) \frac{d\omega_1}{dt} = -(b_1 + b_2)\omega_1 \quad (21)$$

which is a standard first-order system description. Note, however, that in order to arrive at this result, the relation $\omega_1 = \omega_2$ has to be differentiated. This DAE thus includes an implicit differentiation. In the general case, one can investigate how many times (19) has to be differentiated in order to get an explicit expression for dz/dt . This number is called the (differentiation) *index*. Both theoretical analysis and practical experience show that the numerical difficulties encountered when solving a DAE increase with increasing index, see, e.g., the classical reference Brenan et al. (1987) or Campbell et al. (2019). It turns out that mechanical systems in particular give high index models when constructed by joining components, and this has been an obstacle to the use of DAE models. For linear DAE models, the role of the index can be seen more easily. A linear model is given by

$$E \frac{dz}{dt} + Fz = Gu \quad (22)$$

where the matrix E is singular (if E is invertible, multiplication with E^{-1} from the left gives an ordinary differential equation). The system can be transformed by multiplying with P from the left and changing variables with $z = Qw$ (P, Q nonsingular matrices). The transformed model is now

$$PEQ \frac{dw}{dt} + PFQw = PGu \quad (23)$$

If $\lambda E + F$ is nonsingular for some value of the scalar λ , then it can be shown that there is a choice of P and Q such that (23) takes the form

$$\begin{bmatrix} I & 0 \\ 0 & N \end{bmatrix} \begin{bmatrix} dw_1/dt \\ dw_2/dt \end{bmatrix} + \begin{bmatrix} -A & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} u \quad (24)$$

where N is a nilpotent matrix, i.e., $N^k = 0$ for some positive integer k . The smallest such as k turns out to be the index of the DAE. The transformed model (24) thus contains an ordinary differential equation

$$\frac{dw_1}{dt} = Aw_1 + B_1u \quad (25)$$

Using the nilpotency of N , the equation for w_2 can be rewritten

$$w_2 = B_2u - NB_2 \frac{du}{dt} + \dots + (-N)^{k-1} B_2 \frac{d^{k-1}u}{dt^{k-1}} \quad (26)$$

This expression shows that an index $k > 1$ implies differentiation of the input (unless NB_2 happens to be zero). This in turn implies potential difficulties, e.g., if u is a measured signal.

Identification of DAE Models

The extended use of DAE models in modern modeling tools also means that there is a need to use these models in system identification. To fully use system identification theory, one needs a stochastic model of disturbances. The inclusion of such disturbances leads to a class of models described as stochastic differential algebraic equations. The treatment of such models leads to some interesting problems. In the previous section, it was seen that DAE models often contain implicit differentiations of external signals.

If a DAE model is to be well posed, this differentiation must not affect signals modeled as white noise. In Gerdin et al. (2007), conditions are given that guarantee that stochastic DAEs are well posed. There it is also described how a maximum likelihood estimate can be made for DAE models, laying the basis for parameter estimation.

Differential Algebra

For the case where models consist of polynomial equations, it is possible to manipulate them in a very systematic way. The model (19) is then generalized to

$$F(d^n z/dt^n, \dots, dz/dt, z) = 0 \quad (27)$$

where z is now a vector containing an arbitrary mix of inputs, outputs, and internal variables. There is then a theory based on Ritt (1950) that allows the transformation of (27) to a standard form where the properties of the system can be easily determined. The process is similar to the use of Gröbner bases but also includes the possibility of differentiating equations. Of particular interest to identification is the possibility of determining the identifiability of parameters with these tools. The model is then of the form

$$F(d^m y/dt^m, \dots, dy/dt, y, d^n z/dt^n, \dots, dz/dt, z; \theta) = 0 \quad (28)$$

where y contains measured signals, z contains unmeasured variables, and θ is a vector of parameters to be identified, while F is a vector of polynomials in these variables. It was shown in Ljung and Glad (1994) that there is an algorithm giving for each parameter θ_k a polynomial

$$g_k(d^m y/dt^m, \dots, dy/dt, y; \theta_k) = 0 \quad (29)$$

This relation can be regarded as a polynomial in θ_k where all coefficients are expressed in measured quantities. The local or global identifiability will then be determined by the number of solutions. If θ_k is unidentifiable, then no equation

of the form (29) will exist, and this fact will also be demonstrated by the output of the algorithm.

Summary and Future Directions

Grey box modeling is important to capture physical knowledge about models. It can, for instance, be based on bond graphs or Hamiltonian structures. With the increased capabilities of modeling languages grey box modeling will probably become even more important in the future.

Abstract

Since pathogen spillovers and pandemics are unfortunately recurrent in the history of humanity, mathematical approaches to describe and mitigate the spread of infectious diseases have a long tradition. Recently, the COVID-19 pandemic has challenged the scientific community to model, predict, and contain the contagion, especially given the current lack of pharmaceutical interventions such as vaccines and anti-viral drugs targeting the new SARS-CoV-2 coronavirus. The control community has quickly responded by providing new dynamic models of the epidemic outbreak, including both mean-field compartmental models and network-based models, as well as combinations of control approaches and intervention strategies to end the epidemic and recover a new normality. This entry deals with systems-and-control contributions to model epidemics and design effective intervention strategies, with a special focus on the COVID-19 outbreak in Italy.

Keywords

COVID-19 · Epidemics · Epidemiological models · Modeling and control of epidemics · SARS-CoV-2

Introduction

The history of humanity is unfortunately marked by the recurrent appearance of new

lethal pathogens and the subsequent spread of devastating epidemics. To better understand and face this threat, epidemiology studies the patterns of disease evolution in a population. The mathematical foundations of contemporary epidemiology have deep roots in the early twentieth century, but simpler models for disease transmission had been conceived even earlier; see Anderson and May (1991), Bailey (1975), Brauer and Castillo-Chavez (2012), Breda et al. (2012), Diekmann and Heesterbeek (2000), Hethcote (2000), House (2012), Keeling and Eames (2005), Kiss et al. (2017), Nowzari et al. (2016), Pastor-Satorras et al. (2015) and the references therein for a thorough survey.

Predictive mathematical models for epidemics are crucial not only to understand and forecast the evolution of epidemic phenomena but also to plan effective control strategies to contain the contagion. The epidemic models studied in the literature may be divided into two main classes: mean-field compartmental models (Anderson and May 1991; Bailey 1975; Brauer and Castillo-Chavez 2012; Diekmann and Heesterbeek 2000; Hethcote 2000) and network-based models (House 2012; Keeling and Eames 2005; Kiss et al. 2017; Nowzari et al. 2016; Pastor-Satorras et al. 2015). We discuss both in Section “[Mathematical Models and Control Approaches for Epidemics](#)”.

Although mathematical models for epidemics have been studied for a long time, the interest of the control community in the topic awakened only recently (Nowzari et al. 2016), with the exception of the pioneering work in Lee and Leitmann (1994) and Leitmann (1998) on control strategies for endemic infectious diseases. A boost of activity was stirred by the COVID-19 pandemic: in China, in the late 2019, a novel strand of Coronavirus denoted SARS-CoV-2 started to spread, causing a severe and potentially lethal respiratory syndrome labeled as COVID-19. Its high infectiousness enabled the virus to soon spread globally, causing a pandemic: on 8 July 2020, the World Health Organization reported 11,669,259 cases and 539,906 deaths worldwide. Given

the lack of a vaccine and of anti-viral drugs targeting SARS-CoV-2, sound modeling and prediction approaches were crucial to guide the implementation of non-pharmaceutical interventions: quarantine, social distancing and lockdown, testing and contact tracing, isolation, and use of personal protective equipment (Gatto et al. 2020; Giordano et al. 2020; Hellewell et al. 2020; Kucharski et al. 2020). The availability of open data resources (Alamo et al. 2020) favored the emergence of data-driven approaches and models, and the control community explored approaches to “flatten” (Stewart et al. 2020) or even “crush” the epidemic curve.

Italy was among the first non-Asian countries being severely affected by COVID-19. On 24 April 2020, the Italian Chapter of the IEEE Control Systems Society organized an online-workshop on *Modeling and Control of the COVID-19 outbreak: How dynamical models can help control the epidemic* to collect the most recent contributions of systems-and-control researchers to the problem of modeling and predicting the dynamics of contagion evolution. Models and approaches tailored to the specificities of the COVID-19 outbreak were proposed as concrete tools to support policymakers in deciding the best intervention strategies.

This entry illustrates classical mathematical models of epidemic spreading and recently proposed models tailored to the COVID-19 outbreak. It discusses the insight these models provide to help contain the contagion and manage the epidemic phases and surveys novel approaches for the control of epidemics with systems-and-control methodologies.

Mathematical Models and Control Approaches for Epidemics

Compartmental Models

Classical models for epidemic outbreaks are compartmental models; of these, the simplest model capturing the qualitative evolution of an epidemic phenomenon is the SIR model visualized in Fig. 1, introduced in the seminal work (Kermack and McKendrick 1927) to describe the human-to-human transmission of infectious diseases. Compartmental models are mean-field models, where all the parameters represent averaged values over the whole population and do not aim at describing the specific situation of a single individual. They rely on some simplifying assumptions:

- births, deaths (other than those due to the disease), and any other demographic processes either are absent or compensate for each other during the considered period of time, so that the total population is constant;
- the population can be partitioned into mutually exclusive classes, or compartments, depending on the stage of the disease: for the SIR model, each individual is either susceptible to infection (S), infected and infectious (I), and recovered and permanently immune (R); alternatively, R may stand for removed, namely, either recovered and immune or dead;
- the population is large and it is randomly and homogeneously mixed, so that infections occur according to the mass-action law, i.e., depending on the product between the amount of susceptible individuals and of infectious individuals, with rate constant β ;

Modeling of Pandemics and Intervention Strategies: The COVID-19 Outbreak, Fig. 1 Graph representation of the mean-field compartmental epidemiological *SIR* model: Susceptible-Infected-Recovered

- recovery (or recovery, death, and removal) from the infection occurs with rate constant γ .

To understand how the transitions between the various stages are modeled, we can adopt an analogy and represent individuals belonging to different compartments as particles or chemical species, whose concentrations evolve according to given interaction rules or reactions, each associated with a possible transition among compartments. Each “reaction” corresponds to a given “stoichiometric” law and a “reaction” rate. Then, the SIR model visualized in Fig. 1 is described by the equivalent chemical reactions $S + I \xrightarrow{\beta} 2I$ and $I \xrightarrow{\gamma} R$, which correspond to the positive dynamical system

$$\frac{ds}{dt}(t) = -\beta s(t)i(t) \quad (1)$$

$$\frac{di}{dt}(t) = \beta s(t)i(t) - \gamma i(t) \quad (2)$$

$$\frac{dr}{dt}(t) = \gamma i(t) \quad (3)$$

where $s(t)$, $i(t)$, and $r(t)$ denote, respectively, the fraction of susceptible, infected, and recovered individuals (which can be seen as the normalized concentrations of the equivalent chemical species S, I, and R) and $s(t) + i(t) + r(t) \equiv 1$ (the total population is constant, which can be seen as a conservation law). Equation (3) may be neglected, since r does not influence the other variables and its evolution can be obtained by difference: $r(t) = 1 - s(t) - i(t)$. The involved parameters are the transmission coefficient β , depending both on intrinsic features of the pathogen/infection and on the intensity of interactions among individuals, and the recovery/removal coefficient γ , depending on the average time before an individual recovers or dies from the infection; the average duration of infectiousness is $1/\gamma$. The system is positive: starting from nonnegative initial conditions, all the system variables preserve nonnegative values for their whole evolution.

We consider initial conditions with $s(0) \approx 1$, while $0 < i(0) \ll 1$ and $r(0) = 0$.

In the initial stages of the epidemic, the SIR model yields an exponential growth, or decay. In fact, since initially $s \approx 1$,

$$\frac{di}{dt}(t) \approx (\beta - \gamma)i(t), \quad (4)$$

which has the explicit exponential solution

$$i(t) \approx i(0)e^{(\beta - \gamma)t}. \quad (5)$$

Let us define the *basic reproduction number* R_0 , corresponding to the average number of secondary infections caused by a primary case introduced in a fully susceptible population (Anderson and May 1991; Brauer and Castillo-Chavez 2012), as

$$R_0 \doteq \frac{\beta}{\gamma}. \quad (6)$$

Then, Eq. (5) represents an exponential growth if $\beta - \gamma > 0$, namely, $R_0 = \frac{\beta}{\gamma} > 1$, and an exponential decay if $\beta - \gamma < 0$, namely, $R_0 = \frac{\beta}{\gamma} < 1$.

When the complete dynamics in Eqs. (1)–(3) are considered without approximations, including later stages of infection, the value of R_0 still has a key role in determining the epidemic outcome. Denote by $\bar{s}$, $\bar{i}$, and $\bar{r}$ the asymptotic equilibrium value. Starting from an initial condition with $i(0) > 0$, it must be $\bar{s} < s(0)$, since $s(t)$ is monotonically decreasing in view of Eq. (1), while $\bar{r} > r(0)$, since $r(t)$ is monotonically increasing in view of Eq. (3). If $R_0 s(0) < 1$ (hence $R_0 s(t) < 1$ for all $t \geq 0$, being $s(t)$ decreasing), the fraction of infected population decreases, because $\frac{di}{dt} < 0$, as can be seen from (2), until $i(t)$ reaches zero; then there is no outbreak and infections spontaneously decay. Conversely, if $R_0 s(0) > 1$, the fraction of infected population is initially increasing, because $\frac{di}{dt} > 0$. However, since $s(t)$ is decreasing, $R_0 s(t)$ decreases too: it reaches from above the threshold 1 and then goes below. Therefore, the fraction of infected population reaches a peak, at the time t^* such that $R_0 s(t^*) = 1$, and eventually decreases to zero (because, for $t > t^*$, $R_0 s(t) < 1$).

Any equilibrium of the system is such that there are no infected individuals, $\bar{i} = 0$: the

Modeling of Pandemics and Intervention Strategies: The COVID-19 Outbreak, Fig. 2 Graph representation of the mean-field compartmental epidemiological *SEIR* model: Susceptible-Exposed-Infectious-Recovered

generic equilibrium has the form $(\bar{s}, 0, \bar{r})$, with $\bar{s} + \bar{r} = 1$. To ensure stability, the equilibrium value of s must be such that $R_0\bar{s} < 1$.

If we consider the sum of Eqs. (1) and (2), we obtain

$$\frac{ds}{dt}(t) + \frac{di}{dt}(t) = -\gamma i(t). \quad (7)$$

Integration of Eq. (7) yields

$$\int_0^t i(\tau) d\tau = \frac{1}{\gamma} [s(0) - s(t) + i(0) - i(t)]. \quad (8)$$

Also, integrating Eq. (1) divided by s gives

$$\log\left(\frac{s(0)}{s(t)}\right) = \beta \int_0^t i(\tau) d\tau \quad (9)$$

and substituting Eq. (8) into Eq. (9) gives

$$\log\left(\frac{s(0)}{s(t)}\right) = \underbrace{\frac{\beta}{\gamma}}_{R_0} [s(0) - s(t) + i(0) - i(t)]. \quad (10)$$

Rearranging Eq. (10) computed at time $t = t^*$, where t^* is defined above, allows us to compute the peak value $i^{\max}$ of i , which is achieved for $s^* = s(t^*) = \frac{1}{R_0}$:

$$i^{\max} = i(0) + s(0) - \frac{1}{R_0} [1 + \log(R_0 s(0))]. \quad (11)$$

If we start from an initial condition with $r(0) = 0$, hence $s(0) + i(0) = 1$, Eq. (10) allows us to compute the equilibrium value of the susceptible population as the unique positive root of the equation

$$\log\left(\frac{s(0)}{\bar{s}}\right) = R_0[1 - \bar{s}], \quad (12)$$

known as *final size relation*. The quantity $1 - \bar{s} = \bar{r}$, called *attack rate* by the epidemiologists, corresponds to the fraction of the population having experienced the disease during the epidemic.

Several extensions of the SIR model were proposed, taking into account additional infection stages: for instance, the SEIR (Susceptible, Exposed, Infectious, Recovered) model, shown in Fig. 2, considers a latency stage when the infected person is not yet infectious.

The SEIR model is described by the equivalent chemical reactions $S + I \xrightarrow{\beta} E + I$, $E \xrightarrow{\kappa} I$, $I \xrightarrow{\gamma} R$, corresponding to the positive dynamical system

$$\frac{ds}{dt}(t) = -\beta s(t)i(t) \quad (13)$$

$$\frac{de}{dt}(t) = \beta s(t)i(t) - \kappa e(t) \quad (14)$$

$$\frac{di}{dt}(t) = \kappa e(t) - \gamma i(t) \quad (15)$$

$$\frac{dr}{dt}(t) = \gamma i(t) \quad (16)$$

where $s(t)$, $e(t)$, $i(t)$, and $r(t)$ denote, respectively, the fraction of susceptible, exposed, infectious, and recovered individuals and $s(t) + e(t) + i(t) + r(t) \equiv 1$. In this case, all possible equilibria have the form $(\bar{s}, 0, 0, \bar{r})$ with $\bar{s} + \bar{r} = 1$.

More complex models were proposed to better describe the specific features of a given disease; for instance, the SEQIJR model put forth in Gumel et al. (2004) is tailored to SARS. The reader is referred to Anderson and May (1991), Bailey (1975), Brauer and Castillo-Chavez (2012), Diekmann and Heesterbeek (2000), and Hethcote (2000) for further details

on extended compartmental models for epidemic spreading and their analysis.

Network-Based Models

Network-based models embed compartmental models into a graph-theoretic framework: the interacting population is represented by a graph where the nodes are associated with individuals, whose state corresponds to one of the stages in compartmental models (e.g., susceptible, infected, recovered, and immune), and the links among them are associated with human-to-human interactions that can potentially lead to contagion. The transmission rate is no longer an averaged value for a well-mixed population, but is tailored to each specific node, depending on its connectivity degree and on the state of its neighboring nodes. Both stochastic and deterministic population models, and both stochastic and deterministic network models, can be adopted. The models can then describe how the total number of nodes at each of the infection stages evolves over time, depending on the initial conditions and the network topology, by monitoring the fractions of nodes in each stage at each time instant (in a deterministic framework), or the probability that a node belongs to a given stage (in a stochastic framework, based on the evaluation of expectations and moment closures). Network epidemics can also be seen as a percolation phenomenon (House 2012; Pastor-Satorras et al. 2015).

Network-based models also include agent-based models, typically spatially structured, which consider the discrete nature of individuals and their mobility and interaction patterns in a stochastic framework. These models are extremely complex and detailed, since they rely on the construction of a synthetic population reproducing each individual and her/his neighborhood and movements; hence, efficient data-driven computational approaches are needed.

In meta-population models, each node of the network corresponds not to a single individual in the population, but to a group of multiple individuals. We can also consider networked models where each node is associated with a compartmental dynamical system, describing local epi-

demical spreading, and each link represents mobility between local communities, which spreads the epidemic to larger geographic areas (Mei et al. 2017; Paré et al. 2018; Ye et al. 2020).

For more information on epidemics on networks, the reader is referred to House (2012), Keeling and Eames (2005), Kiss et al. (2017), Nowzari et al. (2016), and Pastor-Satorras et al. (2015).

Control Approaches

Several approaches were considered to mitigate the effects of an epidemic outbreak. In a compartmental SIR model, clearly the epidemics can be suppressed by increasing the recovery rate γ (thanks to improved treatment for infected individuals) and decreasing the transmission rate β (which can be achieved by raising awareness, use of personal protective equipment, social distancing, quarantining and isolating infected individuals, or even travel limitations and lockdown), so that $R_0 = \beta/\gamma$ becomes as small as possible, at least smaller than 1 to make the epidemic phenomenon decay.

In network-based epidemic models, with the constraint of a limited budget, one may be interested in optimally investing fixed resources to reduce at best the spreading of the disease, so as to minimize the quantity $\lambda_{\max}(B - \Gamma)$, where $\lambda_{\max}$ denotes the dominant eigenvalue, B is the matrix of infection rates β_{ij} among nodes, and Γ is the diagonal matrix of recovery rates γ_i for the individual nodes. Two possible strategies can be devised for spectral control and optimization: in order to reduce $\lambda_{\max}$, either network nodes or network links can be removed. This corresponds to isolation/quarantine for some individuals (node removal) and to social distancing (link removal).

Optimal control approaches were proposed, relying on Pontryagin's maximum principle, to minimize the cost of the epidemics, which combines the cost of infection and the cost of treatment or vaccination (Bloem et al. 2009; Forster and Gilligan 2007; Hansen and Day 2011; Morton and Wickwire 1974), so as to design an optimal treatment plan, or vaccination plan. Robust control approaches were also proposed to control

the spreading of infectious diseases, seen as an uncertain dynamical system (Lee and Leitmann 1994; Leitmann 1998). Given the complexity of the problem, numerous heuristic feedback control approaches were put forth as well. The reader is referred to Nowzari et al. (2016) for a comprehensive survey of the control of spreading processes.

Modeling and Control of the COVID-19 Outbreak

Several models of the COVID-19 pandemic started to appear in the early 2020. Stochastic transmission models were studied in Hellewell et al. (2020) and Kucharski et al. (2020) to analyze disease transmission and its control by isolation of cases. Also generalized compartmental models were considered: Lin (2020) extends a SEIR model considering perceived contagion risk and cumulative number of cases; Anastassopoulou et al. (2020) analyzes and forecasts the epidemic evolution in China based on a discrete-time SIR model explicitly accounting for dead individuals; and Wu et al. (2020) considers a meta-population SIR model, partitioning the population into age groups, to estimate the clinical severity of COVID-19 from transmission dynamics.

The compartmental SIDARTHE (Susceptible-Infected-Diagnosed-Ailing-Recognized-Threatened-Healed-Extinct; see Fig. 3) model is proposed in Giordano et al. (2020) to understand and predict the COVID-19 epidemic evolution, distinguishing between infected with different severity of illness and between detected and undetected cases of infection. The model highlights the parameters associated with the two main non-pharmaceutical interventions: social distancing and lockdown (which reduce the contagion parameters) and testing and contact tracing (which increase the diagnosis parameters, so that more infection cases are isolated). Different scenarios are explored to assess the effect of various interventions in the Italian case, and the results support the combination of social

distancing with testing and contact tracing so as to rapidly end the epidemic.

A modified SIR model including both recovered and deceased, and taking into account that only a portion of infected individuals can be detected, is proposed in Calafiore et al. (2020). The model predicts the evolution of the contagion in Italy, and in each of its regions, so as to assess the effectiveness of containment and lockdown measures.

An extended SIR model that distinguishes between asymptomatic and symptomatic infected, as well as actual and confirmed cases, is used in Russo et al. (2020) to identify the estimated day zero of the COVID-19 outbreak in Lombardy (Italy).

A compartmental model that highlights the fraction of asymptomatic infectious individuals, considers the COVID-19 spread within and among regions in Italy, and assesses the impact of the adopted interventions is proposed in Di Giamberardino et al. (2020).

A feedback SIR model, with nonlinear transmission rates (Capasso and Serio 1978), is considered in Franco (2020) to study infection-based social distancing and its advantages (the infection peak is reduced, even in the presence of information delays) and disadvantages (extended duration of the epidemic).

The control-oriented SEIR model developed in Casella (2020) stresses the effect of delays and compares the outcomes of different containment policies, in China and in Lazio (Italy). It is shown that mitigation strategies (letting the epidemic run in a controlled way, typically aiming for herd immunity) are likely to fail because they aim at controlling fast unstable dynamics affected by time delays and uncertainties, while suppression strategies can be successful if they are prompt and drastic enough.

Fast multi-shot intermittent lockdown intervals with regular period are proposed in Bin et al. (2020) as an exit strategy from total lockdown to avoid second waves of infection. The suggested switching control strategy is open-loop and robust to delays and uncertainties in measurements, and the parameters of the mitigation strategy are tuned by a slow and robust

Modeling of Pandemics and Intervention Strategies: The COVID-19 Outbreak, Fig. 3 Graph representation of the mean-field compartmental epidemiolog-

ical *SIDARTHE* (Susceptible-Infected-Diagnosed-Ailing-Recognised-Threatened-Healed-Extinct) model. (Reproduced from Giordano et al. 2020)

outer supervisory feedback loop; the proposed approach is successfully tested on compartmental epidemic models ranging from the SIR to the SIDARTHE model (Giordano et al. 2020).

A robust and optimal control strategy for the COVID-19 outbreak is proposed in Köhler et al. (2020) based on model predictive control approaches that dynamically adapt social distancing measures, using the SIDARTHE model (Giordano et al. 2020).

An extended SIR model with specific compartments for socially distanced susceptible and infected (either asymptomatic or symptomatic) individuals is introduced in Gevertz et al. (2020). The analysis of time-varying social distancing strategies reveals that they are effective only if enacted quickly enough, and there is a critical intervention delay after which they have little effect; moreover, periodic relaxation strategies can be effective but are extremely fragile to small errors in timing or parameters, while gradual relaxation substantially improves the epidemic situation, but the rate of relaxation needs to be carefully chosen to prevent a second outbreak.

Economists modeled the epidemic resorting to a SIR model that incorporates the optimizing behavior of rational agents, incentives influencing the transitions, and externalities representing restrictive government interventions (Garibaldi et al. 2020): agent-based rational decision-making, leading to a decentralized epidemic equilibrium, yields outcomes consistent with the original model in Kermack and McKendrick (1927).

The work in Gatto et al. (2020) analyzes the local-global effect of containment measures by studying a meta-population SEIR-like model that interconnects the epidemics in different Italian provinces to model the spatial spreading of the outbreak; the resolution that models the disease spread at the appropriate geographical scale allows for both spatial and temporal design of containment measures and makes it possible to forecast the medical resources and infrastructures needed. The same spatially explicit approach is adopted in Bertuzzo et al. (2020) to suggest appropriate relaxations of the containment measures adopted in Italy, discussing possible

options such as tracing and testing, stop-and-go lockdown enforcement, and delayed lockdown relaxations.

A networked meta-population SIR model is proposed in Della Rossa et al. (2020) to describe the Italian epidemics by looking at the country as a network of regions, each with different epidemic parameters; this reveals the different regional effects of the adopted countermeasures, as well as the important impact of regional heterogeneity on the outbreak evolution, and suggests that differentiated (but coordinated) feedback interventions enforced at a regional level could be particularly beneficial.

A meta-population networked model is also proposed in Zino et al. (2020), focused on the role of activity and mobility in the COVID-19 outbreak in Italy: the model considers the reduction in activity (to study the effect of “stay at home” policies) and mobility within and between provinces (to study the effect of mobility limitations, travel bans, and isolation of red zones), as well as isolation (to study the effect of quarantine and testing).

A different methodology is proposed in Fanti et al. (2020), where a multi-criteria approach is adopted for COVID-19 risk assessment in different lockdown scenarios, focusing on urban district lockdowns in Puglia (Italy).

Several epidemic scenarios with different testing policies and mobility restrictions are outlined in Dahleh et al. (2020), where a network SIR-like model is used to explore control approaches based on testing, distancing, and quarantining.

The challenges of forecasting the spread of COVID-19 using different models (exponential, SIR, and Hawkes self-exciting branching process) are discussed in Bertozzi et al. (2020).

Model accuracy and validation The proposed models were tested against official epidemiological data provided by local and national governments. In spite of the large noise and uncertainty affecting the available data on the COVID-19 epidemic evolution, the proposed models, with the parameters fit based on real data, proved to

be able to accurately reproduce and predict the outbreak dynamics.

Summary and Future Directions

We provided an overview of dynamic models, both compartmental and network-based, to describe, predict, and control the evolution of epidemics, with a special focus on the models and intervention strategies tailored to the ongoing COVID-19 pandemic.

Models proved to be a precious tool not only to forecast epidemic phenomena but also to assess and predict the effectiveness of different policies and countermeasures. Non-pharmaceutical strategies are lockdown and social distancing (including the widespread use of personal protective equipment), population-scale testing, and contact tracing. Each strategy has some fragilities. The impact of lockdown on the economy, as well as on mental health (Torales et al. 2020), needs to be taken into account, while the effectiveness and correct use of personal protective equipment has been long debated. Testing strategies need to cope with a limited availability of tests; this problem is studied in Drakopoulos and Randhawa (2020) using a resource allocation approach, and it is shown that it may prove efficient to release less accurate tests when the epidemic is picking up and then more accurate tests as they become available. Contact tracing requires the adoption of individual tracking and monitoring via apps that generate privacy concerns.

In this complex situation, outlining different scenarios and predictions based on the available data and on solid mathematical modeling can inform and guide policymakers deciding how to handle the ongoing pandemic. Therefore, we are convinced that the contribution of the systems-and-control community will be valuable to contain the COVID-19 outbreak, as well as future pandemics. At the same time, the peculiar characteristics of epidemiological models pose important theoretical challenges that are pushing out

the frontiers of the methodological tools developed by our community.

Abstract

Petri net is a generic term used to designate a broad family of related formalisms for discrete event views of (dynamic) systems (DES), all sharing some basic relevant features, such as *minimality* in the number of primitives, *locality* of the states and actions (with consequences for model construction), or *temporal realism*. The global state of a system is obtained by the juxtaposition of the different local states. We should initially distinguish between *autonomous* formalisms and those *extended by interpretation*. Models in the latter group are obtained by restricting the underlying autonomous behaviors by means

of constraints that can be related to different kinds of external events, in particular to time. This article first describes *place/transition* nets (PT-nets), by default simply called Petri nets (PNs). Other formalisms are then mentioned. As a system theory modeling paradigm for concurrent DES, Petri nets are used in a wide variety of application fields.

Keywords

Condition/event nets (CE-nets) · Continuous petri nets (CPNs) · Diagrams · Fluidization · Grafcet · Hybrid petri nets (HPNs) · Marking petri nets · Place/transition nets (PT-nets) · High-level Petri nets (HLPNs)

Introduction

Petri nets (PNs) are able to model concurrent and distributed DES (► [“Models for Discrete Event Systems: An Overview”](#)). They constitute a powerful family of formalisms with different expressive purposes and power. They may be applied to, inter alia, modeling, logical analysis, performance evaluation, parametric optimization, dynamic control (minimum makespan, supervisory control, or other kinds), diagnosis, and implementation issues (eventually fault tolerant). Hybrid and continuous PNs are particularly useful when some parts of the system are highly populated. Being *multidisciplinary*, formalisms belonging to the Petri nets paradigm may cover several phases of the life cycle of complex DES.

A Petri net can be represented as a bipartite directed graph provided with arcs inscriptions; alternatively, this structure can be represented in algebraic form using some matrices. As in the case of differential equations, an initial condition or state should be defined in order to represent a dynamic system. This is done by means of an initial distributed state. The English translation of the Carl Adam Petri’s seminal work, presented in 1962, is Petri (1966).

Untimed Place/Transition Net Systems

A place/transition net (PT-net) can be viewed as $\mathcal{N} = \langle P, T, \mathbf{Pre}, \mathbf{Post} \rangle$, where:

- P and T are disjoint and finite nonempty sets of *places* and *transitions*, respectively.
- $\mathbf{Pre}$ and $\mathbf{Post}$ are $|P| \times |T|$ sized, natural-valued (zero included), and incidence matrices. The net is said to be *ordinary* if $\mathbf{Pre}$ and $\mathbf{Post}$ are valued on $\{0, 1\}$. Weighted arcs permit the abstract modeling of *bulk* services and arrivals.

A PT-net is a structure. The $\mathbf{Pre}$ ($\mathbf{Post}$) function defines the connections from places to transitions (transitions to places). Those two functions can alternatively be defined as *weighted flow* relations (nets as graphs). Thus, PT-nets can be represented as *bipartite directed graphs* with *places* (p , using circles) and *transitions* (t , using bars or rectangles) as nodes: $\mathcal{N} = \langle P, T, F, W \rangle$, where $F \subseteq (P \times T) \cup (T \times P)$ is the *flow relation* (set of directed arcs, with $\text{dom}(F) \cup \text{range}(F) = P \cup T$) and $W : F \rightarrow \mathbb{N}^+$ assigns a natural weight to each arc.

The net structure represents the *static* part of the DES model. Furthermore, a “distributed state” is defined over the set of places, known as the *marking*. This is “numerically quantified” (not in an arbitrary alphabet, as in automata), associating *natural* values to the local state variables, the places. If a place p has a value v (i.e., $\mathbf{m}(p) = v$), it is said to have v *tokens* (frequently depicted in graphic terms with v black dots or just the number inside the place). The places are “state variables,” while the markings are their “values”; the *global state* is defined through the concatenation of local states. The net structure, provided with an initial marking, to be denoted as $(\mathcal{N}, \mathbf{m}_0)$, is a *Petri net system*, or *marked Petri net*.

The last two basic PN constructions in Fig. 1 (*join* and *fork*) do not appear in finite-state machines; moreover, the arcs may be valued with natural numbers. The dynamic behavior of the net

Modeling, Analysis, and Control with Petri Nets, Fig. 1 Most basic PN constructions: The logical OR is present around places, in *choices* (or branches) and

attributions (or meets); the logical AND is formed around transitions, in *joins* (or waits or *rendezvous*) and *forks* (or splits)

Modeling, Analysis, and Control with Petri Nets, Fig. 2 Only transitions *b* and *c* are initially enabled. The results of firing *b* or *c* are shown subsequently

system (trajectories with changes in the marking) is produced by the firing of transitions, some “local operations” which follows very simple rules.

Markings in net systems evolve according to the following *firing* (or *occurrence*) rules (see Fig. 2):

- A transition is said to be *enabled* at a given marking if each input place has at least as many tokens as the weight of the arc joining them.
- The *firing* or *occurrence* of an enabled transition is an instantaneous operation that removes from (adds to) each input (output) place a number of tokens equal to the weight of the arc joining the place (transition) to the transition (place).

The precondition of a transition can be seen as the resources required for the transition to be fired. The weight of the arc from a place to a transition represents the number of resources to be *consumed*. The post-condition defines the number resources *produced* by the firing of the transition.

This is made explicit by the weights of the arcs from the transition to the places. Three important observations should be taken into account:

- The underlying logic in the firing of a transition is non-monotonic! It is a *consumption/production* logic.
- Enabled transitions are never *forced* to fire: This is a form of *non-determinism*.
- An *occurrence sequence* is a sequence of fired transitions $\sigma = t_1 \dots t_k$. In the evolution from m_0 , the reached marking m can be easily computed as:

$$m = m_0 + C \cdot \sigma, \quad (1)$$

where $C = \text{Post} - \text{Pre}$ is the *token flow* matrix (*incidence* matrix if $\mathcal{N}$ is self-loop free) and σ the firing count vector corresponding to σ . Thus m and σ are vectors of natural numbers.

The previous equation is the *state-transition* equation (frequently known as the *fundamental* or, simply, *state* equation). Nevertheless, two important remarks should be made:

- It represents a necessary but not sufficient condition for reachability; the problem is that the existence of a σ does not guarantee that a corresponding sequence σ is firable from m_0 ; thus, certain solutions – called *spurious* (Silva et al. 1998) – are not reachable. This implies that – except in certain net system subclasses – only semi-decision algorithms can usually be derived.
- All variables are natural numbers, which imply computational complexity.

It should be pointed out that in finite-state machines, the state is a single variable taking values in a symbolic unstructured set, while in PT-net systems, it is structured as a vector of nonnegative integers. This allows analysis techniques that do not require the enumeration of the state space.

At a structural level, observe that the *negation* is missing in Fig. 1; its inclusion leads to the so-called inhibitor arcs, an extension in expressive power. In its most basic form, if the place at the origin of an inhibitor arc is marked, it “inhibits” the enabling of the target transition. PT-net systems can model infinite-state systems, but not Turing machines. PT-net systems provided with inhibitor arcs (or *priorities* on the firing of transitions) can do it.

With this conceptually simple formalism, it is not difficult to express basic synchronization schemas (Fig. 3). All the illustrated examples use *joins*. When *weights* are allowed in the arcs, another kind of synchronization appears: Several copies of the same resource are needed (or produced) in a single operation. Being able to express *concurrency* and *synchronization*, when viewing the system at a higher level, it is possible to build *cooperation* and *competition* relationships.

Analysis and Control of Untimed PT Models

The behavior of a concurrent (eventually distributed) system is frequently difficult to understand and control. Thus, misunderstandings

and mistakes are frequent during the design cycle. A way of cutting down the cost and duration of the design process is to express in a formalized way properties that the system should enjoy and to use formal proof techniques. Errors can be eventually detected close to the moment they are introduced, reducing their propagation to subsequent stages. The goal in *verification* is to ensure that a given system is correct with respect to its specification (perhaps expressed in temporal-logic terms) or to a certain set of predetermined properties.

Among the most basic qualitative properties of “net systems” are the following: (1) *reachability* of a marking from a given one; (2) *boundedness*, characterizing finiteness of the state space; (3) *liveness*, related to potential fireability of all transitions starting on an arbitrary reachable marking (*deadlock-freeness* is a weaker condition in which only global infinite fireability of the net system model is guaranteed, even if some transitions no longer fire); (4) *reversibility*, characterizing recoverability of the initial marking from any reachable one; and (5) *mutual exclusion of two places*, dealing with the impossibility of reaching markings in which both places are simultaneously marked.

All the above are *behavioral* properties, which depend on the net system $(\mathcal{N}, m_0)$. In practice, sometimes problems with a net model are rooted in the net structure; thus, the study of the *structural* counterpart of certain behavioral properties may be of interest. For example, a “net” is *structurally bounded* if it is bounded for any initial marking; a “net” is *structurally live* if an initial marking exists that make the net system live (otherwise stated, it reflect non-liveness for arbitrary initial markings, a pathology of the net).

Basic techniques to analyze net systems include (1) *enumeration*, in its most basic form based on the construction of a *reachability graph* (a sequentialized view of the behavior). If the net system is not bounded, losing some information, a finite *coverability graph* can be constructed; (2) *transformation*, based on an iterative rewriting process in which a net system enjoys a certain property if and only if a transformed (“simpler” to analyze) one also

Modeling, Analysis, and Control with Petri Nets,
Fig. 3 Basic synchronization schemes: (1) Join or rendezvous, RV; (2) Semaphore, S; (3) Mutual exclusion semaphore (mutex), R, representing a shared resource; (4) Symmetric RV built with two semaphores; (5) Asymmetric RV built with two semaphores (master/slave); (6) Fork-join (or par-begin/par-end); (7) Non-recursive sub-program (places i and j cannot be simultaneously marked

– must be in mutex – to remember the returning point; for simplicity, it is assumed that the subprogram is single input/single output); (8) Guard (a self-loop from a place through a transition); its role is like a traffic light. If at least one token is present at the place, it allows the evolution, but it is not consumed. Synchronizations can also be modeled by the weights associated with the arcs going to transitions

does. If the new system is easier to analyze, and the transformation is computationally cheap, the process may be extremely interesting; (3) *structural*, based on graph properties, or in mathematical programming techniques rooted on the state equation; (4) *simulation*, particularly interesting for gaining certain confidence about the absence of certain pathological behaviors. Analysis strategies combining all these kinds of techniques are extremely useful in practice.

Reachability techniques provide sequentialized views for a particular initial marking.

Moreover they suffer from the so-called *state explosion* problem. The reduction of this computational issue leads to techniques such as *stubborn set* methods (smaller, equally informative reachability graphs), also to non-sequentialized views such as those based on *unfoldings*. Transformation techniques are extremely useful, but not complete (i.e., not all net systems can be reduced in a practical way). In most cases, structural techniques only provide necessary or sufficient conditions (e.g., a sufficient condition for deadlock-freeness, a

necessary condition for reversibility, etc.), but not a full characterization. As already pointed out, a limitation of methods based on the state equation for analyzing net systems is the existence of non-reachable solutions (the so-called spurious solutions). In this context, three kinds of related notions that must be differentiated are the following: (1) some natural *vectors* (left and right annullers of the token flow matrix, **C**: *P-semiflows* and *T-semiflows*), (2) some invariant *laws* (*token conservation* and *repetitive behaviors*), and (3) some peculiar *subnets* (*conservative* and *consistent* components, generated by the subsets of nodes in the P- and T-semiflows, respectively).

More than analysis, *control* leads to synthesis problems. The idea is to *enforce* the given system in order to fulfill a specification (e.g., to enforce certain mutual exclusion properties). Technically speaking, the idea is to “add” some elements in order to constrain the behavior in such a way that a correct execution is obtained. Questions related to control, observation, diagnosis, or identification are all areas of ongoing research.

With respect to classical control theory, there are two main differences: Models are DES and untimed (autonomous, fully nondeterministic, eventually labeling the transitions in order to be able to consider the PN languages). Let us remark that for control purposes, the transitions should be partitioned into *controllable* (when enabled, you can either force or block the firing) and *uncontrollable* (if enabled, the firing is nondeterministic). A natural approach to synthesize a control is to start modeling the plant dynamics (by means of a PN, **P**) and adopting a specification for the desired closed-loop system (**S**). The goal is to compute a controller (**L**) such that **S** equals the parallel-composition of **P** and **L**; in other words, controllers (called “supervisors”) are designed to ensure that only behaviors consistent with the specification may occur. The previous equality is not always possible, and the goal is usually relaxed to minimally limit the behavior within the specified legality (i.e., to compute *maximally permissive* controllers). For an approach in the framework of finite-state machines and

regular languages, see ► [“Supervisory Control of Discrete-Event Systems”](#). The synthesis in the framework of Petri nets and having goals as enforcing some generalized mutual exclusions constraints in markings or avoiding deadlocks, for example, can be efficiently approached by means of the so named *structure theory*, based on the direct exploitation of the structure of the net model (using graph or mathematical programming theories and algorithms, where the initial marking is a parameter).

Similarly, transitions (or places) can be partitioned into *observable* and *unobservable*. Many *observability* problems may be of interest, for example, observing the firing of a subset of transitions to compute the subset of markings in which the system may be. Related to observability, *diagnosis* is the process of detecting a failure (any deviation of a system from its intended behavior) and identifying the cause of the abnormality. *Diagnosability*, like observability or controllability, is a logical criterion. If a model is diagnosable with respect to a certain subset of possible faults (i.e., it is possible to detect the occurrence of those faults in finite time), a diagnoser can be constructed (see section “Diagnosis and Diagnosability Analysis of Petri Nets” in ► [“Diagnosis of Discrete Event Systems”](#)). *Identification* of DES is also a question that has required attention in recent years. In general, the starting point is a behavioral observation, the goal being to construct a PN model that generates the observed behavior, either from examples/counterexamples of its language or from the structure of a reachability graph. So the results are *derived* models, not human-made models (i.e., not made by designers).

The Petri Nets Modeling Paradigm

Along the *life cycle* of DES, designers may deal with basic modeling, analysis, and synthesis from different perspectives together with implementation and operation issues. Thus, the designer may be interested in expressing the

basic structure, understanding untimed possible behaviors, checking logic properties on the model when provided with some timing (e.g., in order to guarantee if a certain reaction is possible before 3 ms; something relevant in real-time systems), computing some performance indices on timed models (related to the throughput in the firing of a given transition, or to the length of a waiting line, expressed as the number of tokens in a place), computing a schedule or control that optimizes a certain objective function, decomposing the model in order to prepare an efficient implementation, efficiently determining redundancies in order to increase the degree of fault tolerance, etc. For these different tasks, different formalisms may be used. Nevertheless, it seems desirable to have a *family* of related formalisms rather than a collection of “unrelated” or weakly related formalisms. The expected advantages would include *coherence* among models usable in different phases, *economy* in the transformations, and *synergy* in the development of models and theories.

Other Untimed PN Formalisms: Levels of Expressive Power

PT-net systems are more powerful than *condition/event* (CE) systems, roughly speaking the basic seminal formalism of Carl Adam Petri in which places can be marked only with zero or one token (Boolean marking). CE-systems can model only finite-state systems. As already said, “extensions” of the expressive power of untimed PT-net systems to the level of Turing machines are obtained by adding inhibitor arcs or priorities to the firing of transitions.

An important idea is adding the notion of *individuals* to tokens (e.g., from anonymous to labeled or colored tokens). Information in tokens allows the objects to be named (they are no longer indistinguishable) and dynamic associations to be created. Moving from PT-nets to so-called high-level PNs (HLPNs) is something like “moving from assembler to high-level programming languages” or, at the computational level, like “moving from pure numerical to a symbolic level.” There are many proposals in this respect, the

more important being predicate/transition nets and colored PNs. Sometimes, this type of abstraction has the same theoretical expressiveness as PT-net systems (e.g., colored PNs if the number of colors is finite); in other words, high-level views may lead to more compact and structured models while keeping the same theoretical expressive power of PT-nets (i.e., we can speak of “abbreviations,” not of “extensions”). In other cases, *object-oriented* concepts from computer programming are included in certain HLPNs. The analysis techniques of HLPNs can be approached with techniques based on enumeration, transformation, or structural considerations and simulation, generalizing those developed for PT-net systems.

Extending Net Systems with External Events and Time: Nonautonomous Formalisms

When dealing with net systems that interact with some specific environment, the marking evolution rule must be slightly modified. This can be done in an enormous number of ways, considering external events and logical conditions as inputs to the net model, in particular some depending on time. The same interpretation given to a graph in order to define a *finite-state diagram* can be used to define a *marking diagram*, a formalism in which the key point is to recognize that the state is now numerical (for PT-net systems) and distributed. For example, drawing a parallel with Moore automata, the transitions should be labeled with logical conditions and events, while unconditional actions are associated with the places. If a place is marked, the associated actions are emitted.

Even if only *time-based interpretations* are considered, there are a large number of successful proposals for formalisms. For example, it should be specified if time is associated with the firing of transitions (T-timing may be atomic or in three phases), the residence of tokens in places (P-timed), and the arcs of the net, as tags to the tokens, etc. Moreover, even for T-timed models, there are many ways of defining the timing: *time intervals*, *stochastic* or *possibilistic* forms, and the *deterministic* case as a particular one. If the

firing of transitions follows *exponential* pdfs, and the conflict resolution follows the *race* policy (i.e., fire in conflicts the first that ends the task, not a *preselection* policy), the underlying Markov chain described is isomorphic to the reachability graph (due to the Markovian “memoryless” property). Moreover, the addition of *immediate* transitions (whose firing is instantaneous) enriches the practical modeling possibilities, eventually complicating the analysis techniques. Timed models are used to compute minimum and maximum time delays (when time intervals are provided, in real-time problems) or performance figures (throughput, utilization rate of resources, average number of tokens – clients – in services, etc.). For performance evaluation, there is an array of techniques to compute bounds, approximated values, or exact values, sometimes generalizing those that are used in certain queueing network classes of models. Simulation techniques are frequently very helpful in practice to produce an *educated guess* about the expected performance. Time constraints on Petri nets may change logical properties of models (e.g., mutual exclusion constraints, deadlock-freeness, etc.), calling for new analysis techniques. For example, certain timings on transitions can transform a live system into a non-live one (if to the net system in Fig. 2 are associated deterministic times to transitions and a race policy with the time associated with transition *c* smaller than that of transition *a*, transition *b* cannot be fired, after firing transition *d*; thus it is non-live, while the untimed model was live). By the addition of some time constraints, the transformation of a non-live model into a live one is also possible. So additional analysis techniques need to be considered, redefining the state, now depending also on time, more than just on the marking.

Finally, as in any DES, the optimal control of timed Petri net models (scheduling, sequencing, etc.) may be approached by techniques as dynamic programming or perturbation analysis (presented in the context of queueing networks and Markov chains, see ► [“Perturbation Analysis of Discrete Event Systems”](#)). In practice, those problems are frequently approached by means of some partially heuristic strategies. About the

diagnosis of timed Petri nets, see ► [“Diagnosis of Discrete Event Systems”](#). Of course, all these tasks can be done with HLPNs.

Fluid and Hybrid PN Models

Different ideas may lead to different kinds of *hybrid* PNs. One is to *fluidize* (here to relax the natural numbers of discrete markings into the nonnegative reals) the firing of transitions that are “most time” enabled. Then the relaxed model has *discrete* and *continuous* transitions, thus also *discrete* and *continuous* places. If all transitions are fluidized, the PN system is said to be *fluid* or *continuous*, even if technically it is a hybrid one. In this approach, the main goal is to try to overcome the *state explosion* problem inherent to enumeration techniques. Proceeding in that way, some computationally NP-hard problems may become much easier to solve, eventually in polynomial time. In other words, *fluidization* is an abstraction that tries to make tractable certain real-scale DES problems (► [“Discrete Event Systems and Hybrid Systems, Connections Between”](#)).

When transitions are timed with the so-called *infinite server* semantics, the PN system can be observed as a time differentiable *piecewise affine* system. Thus, even if the relaxation “simplifies” computations, it should be taken into account that continuous PNs with infinite server semantics are able to simulate Turing machines. From a different perspective, the steady-state throughput of a given transition may be non-monotonic with respect to the firing rates or the initial marking (e.g., if faster or more machines are used, the uncontrolled system may be slower); moreover, due to the important expressive power, *discontinuities* may even appear with respect to continuous design parameters as firing rates, for example.

An alternative way to define hybrid Petri nets is a generalization of *hybrid automata*: The net system is a DES, but sets of differential equations are associated to the marking of places. If a place is marked, the corresponding differential equations contribute to define its evolution.

Summary and Future Directions

Petri nets designate a broad family of related DES formalisms (a modeling paradigm) each one specifically tailored to approach certain problems. Conceptual simplicity coexists with powerful modeling, analysis, and synthesis capabilities. From a control theory perspective, much work remains to be done for both untimed and timed formalisms (remember, there are many different ways of timing), particularly when dealing with optimal control of timed models. In engineering practice, approaches to the latter class of problems frequently use heuristic strategies. From a broader perspective, future research directions include improvements required to deal with controllability and the design of controllers, with observability and the design of observers, with diagnosability and the design of diagnosers, and with identification. This work is not limited to the strict DES framework, but also applies to analogous problems relating to relaxations into *hybrid* or *fluid* approximations (particularly useful when high populations are considered). The distributed nature of system is more and more frequent and is introducing new constraints, a subject requiring serious attention. In all cases, different from firing languages approaches, the so named *structure theory* of Petri nets should gain more interest.

Recommended Reading

Topics related to PNs are considered in well over a hundred thousand papers and reports.

The first generation of books concerning this field is Brauer (1980), immediately followed by Starke (1980), Peterson (1981), Brams (1983), Reisig (1985), and Silva (1985). The fact that they are written in English, French, German, and Spanish is proof of the rapid dissemination of this knowledge. Most of these books deal essentially with PT-net systems. Complementary surveys are Murata (1989), Silva (1993), and David and Alla (1994), the latter also considering some continuous and hybrid models. Concerning high-level PNs, Jensen and Rozenberg (1991) is a selection of papers covering the main developments during the 1980s. Jensen and Kristensen (2009) focus on state space methods and simulation where elements of timed models are taken into account, but performance evaluation of stochastic systems is not covered. Approaching the present days, relevant works written with complementary perspectives include inter alia, Girault and Valk (2003), Diaz (2009), David and Alla (2010), and Seatzu et al. (2013). The consideration of time in nets with an emphasis on performance and performability evaluation is addressed in monographs such as Ajmone Marsan et al. (1995), Bause and Kritzinger (1996), Balbo and Silva (1998), and Haas (2002), while timed models under different fuzzy interpretations are the subject of Cardoso and Camargo (1999). Structure-based approaches to control PN models is the main subject in Iordache and Antsaklis (2006) or Chen and Li (2013). Different kinds of hybrid PN models are studied in Di Febbraro et al. (2001), Villani et al. (2007), and David and Alla (2010), while a broad perspective about modeling, analysis, and control of fluid (or continuous) – untimed and timed – PNs is provided by Silva et al. (2011).

DiCesare et al. (1993) and Desrochers and Al-Jaar (1995) are devoted to the applications of PNs to manufacturing systems. A comprehensive updated introduction to business process systems and PNs can be found in van der Aalst and Stahl (2011). Special volumes dealing with other monographic topics are, for example, Billington et al. (1999), Agha et al. (2001), and Cortadella et al. (2002). An application domain for Petri nets emerging over the last two decades is

systems biology, a model-based approach devoted to the analysis of biological systems (Wingender 2011; Koch et al. 2011). Furthermore, it should be pointed out that Petri nets have also been employed in many other application domains (e.g., from logistics to musical systems).

For an overall perspective of the field over the five decades that have elapsed since the publication of Carl Adam Petri's PhD thesis, including historical, epistemological, and technical aspects, see Silva (2013). An overview of the historical development of the field of Petri nets (PNs) from a Systems Theory and Automatic Control perspective is provided in Giua and Silva (2018). Intentionally not meant to be comprehensive, it outlines, through selected representative topics, some of the conceptual issues studied in the literature.

Information and Systems Engineering, Boston
University, Brookline, MA, USA

Abstract

This article provides an introduction to discrete event systems (DES) as a class of dynamic systems with characteristics significantly distinguishing them from traditional time-driven systems. It also overviews the main modeling frameworks used to formally describe the operation of DES and to study problems related to their control and optimization.

Introduction

Discrete event systems (DES) form an important class of dynamic systems. The term was introduced in the early 1980s to describe a DES in terms of its most critical feature: the fact that its behavior is governed by *discrete events* which occur asynchronously over time and which are solely responsible for generating state transitions. In between event occurrences, the state of a DES is unaffected. Examples of such behavior abound in technological environments, including computer and communication networks, manufacturing systems, transportation systems, logistics, and so forth. The operation of a DES is largely regulated by rules which are often unstructured and frequently human-made, as in initiating or terminating activities and scheduling the use of resources through controlled events (e.g., turning equipment “on”). On the other hand, their operation is also subject to uncontrolled randomly occurring events (e.g., a spontaneous equipment failure) which may or may not be observable through sensors. It is worth pointing out that the term “discrete event dynamic system” (DEDS) is also commonly used to emphasize the importance of the dynamical behavior of such systems (Ho 1991; Cassandras and Lafortune 2008).

There are two aspects of a DES that define its behavior:

1. The variables involved are both continuous and discrete, sometimes purely symbolic, i.e., nonnumeric (e.g., describing the state of a traffic light as “red” or “green”). This renders traditional mathematical models based on differential (or difference) equations inadequate and related methods based on calculus of limited use.
2. Because of the asynchronous nature of events that cause state transitions in a DES, it is neither natural nor efficient to use time as a synchronizing element driving its dynamics. It is for this reason that DES are often referred to as *event driven*, to contrast them to classical *time-driven* systems based on the laws

of physics; in the latter, as time evolves state, variables such as position, velocity, temperature, voltage, etc., also continuously evolve. In order to capture event-driven state dynamics, however, different mathematical models are necessary.

In addition, uncertainties are inherent in the technological environments where DES are encountered. Therefore, associated mathematical models and methods for analysis and control must incorporate such uncertainties. Finally, complexity is also inherent in DES of practical interest, usually manifesting itself in the form of combinatorially explosive state spaces. Although purely analytical methods for DES design, analysis, and control are limited, they have still enabled reliable approximations of their dynamic behavior and the derivation of useful structural properties and provable performance guarantees. Much of the progress made in this field, however, has relied on new paradigms characterized by a combination of mathematical techniques, computer-based tools, and effective processing of experimental data.

Event-driven and time-driven system components are often viewed as coexisting and interacting and are referred to as *hybrid systems* (separately considered in the Encyclopedia, including the article ► [Discrete Event Systems and Hybrid Systems, Connections Between](#)). Arguably, most contemporary technological systems are combinations of time-driven components (typically, the physical parts of a system) and event-driven components (usually, the computer-based controllers that collect data from and issue commands to the physical parts).

Event-Driven vs. Time-Driven Systems

In order to explain the difference between time-driven and event-driven behavior, we begin with the concept of “event.” An event should be thought of as occurring instantaneously and causing transitions from one system state value to another. It may be identified with an action

(e.g., pressing a button), a spontaneous natural occurrence (e.g., a random equipment failure), or the result of conditions met by the system state (e.g., the fluid level in a tank exceeds a given value). For the purpose of developing a model for DES, we will use the symbol e to denote an event. Since a system is generally affected by different types of events, we assume that we can define a discrete *event set* E with $e \in E$.

In a classical system model, the “clock” is what drives a typical state trajectory: with every “clock tick” (which may be thought of as an “event”), the state is expected to change, since continuous state variables continuously change with time. This leads to the term *time driven*. In the case of time-driven systems described by continuous variables, the field of systems and control has based much of its success on the use of well-known differential-equation-based models, such as

$$\mathbf{R}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \quad (1)$$

$$\mathbf{y}(t) = \mathbf{g}(\mathbf{x}(t), \mathbf{u}(t), t), \quad (2)$$

where (1) is a (vector) state equation with initial conditions specified and (2) is a (vector) output equation. As is common in system theory, $\mathbf{x}(t)$ denotes the state of the system, $\mathbf{y}(t)$ is the output, and $\mathbf{u}(t)$ represents the input, often associated with controllable variables used to manipulate the state so as to attain a desired output. Common physical quantities such as position, velocity, temperature, pressure, flow, etc., define state variables in (1). The state generally changes as time changes, and, as a result, the time variable t (or some integer $k = 0, 1, 2, \dots$ in discrete time) is a natural independent variable for modeling such systems.

In contrast, in a DES, time no longer serves the purpose of driving such a system and may no longer be an appropriate independent variable. Instead, at least some of the state variables are discrete, and their values change only at certain points in time through instantaneous transitions which we associate with “events.” If a clock is used, consider two possibilities: (i) At every clock tick, an event e is selected from

the event set E (if no event takes place, we use a “null event” as a member of E such that it causes no state change), and (ii) at various time instants (not necessarily known in advance or coinciding with clock ticks), some event e “announces” that it is occurring. Observe that in (i) state transitions are *synchronized* by the clock which is solely responsible for any possible state transition. In (ii), every event $e \in E$ defines a distinct process through which the time instants when e occurs are determined. State transitions are the result of combining these *asynchronous* concurrent event processes. Moreover, these processes need not be independent of each other. The distinction between (i) and (ii) gives rise to the terms *time-driven* and *event-driven* systems, respectively.

Comparing state trajectories of time-driven and event-driven systems is useful in understanding the differences between the two and setting the stage for DES modeling frameworks. Thus, in Fig. 1, we observe the following: (i) For the

time-driven system shown, the state space X is the set of real numbers $\mathbb{R}$, and $x(t)$ can take any value from this set. The function $x(t)$ is the solution of a differential equation of the general form $\dot{x}(t) = f(x(t), u(t), t)$, where $u(t)$ is the input. (ii) For the event-driven system, the state space is some discrete set $X = \{s_1, s_2, s_3, s_4\}$. The sample path can only jump from one state to another whenever an event occurs. Note that an event may take place, but not cause a state transition, as in the case of e_4 . There is no immediately obvious analog to $\dot{x}(t) = f(x(t), u(t), t)$, i.e., no mechanism to specify how events might interact over time or how their time of occurrence might be determined. Thus, a large part of the early developments in the DES field has been devoted to the specification of an appropriate mathematical model containing the same expressive power as (1)–(2) (Cassandras and Lafortune 2008; Baccelli et al. 1992; Glasserman and Yao 1994).

We should point out that a time-driven system with continuous state variables, usually modeled through (1)–(2), may be abstracted as a DES through some form of discretization in time and quantization in the state space. We should also point out that discrete *event* systems should not be confused with discrete *time* systems. The class of discrete time systems contains both time-driven and event-driven systems.

Models for Discrete Event Systems: An Overview,
Fig. 1 Comparison of time-driven and event-driven state trajectories

Timed and Untimed Models of Discrete Event Systems

Returning to Fig. 1, instead of constructing the piecewise constant function $x(t)$ as shown, it is convenient to simply write the timed sequence of events $\{(e_1, t_1), (e_2, t_2), (e_3, t_3), (e_4, t_4), (e_5, t_5)\}$ which contains the same information as the state trajectory. Assuming that the initial state of the system (s_2 in this case) is known and that the system is “deterministic” in the sense that the next state after the occurrence of an event is unique, we can recover the state of the system at any point in time and reconstruct the DES state trajectory. The set of all possible timed sequences of events that a given system

can ever execute is called the *timed language* model of the system. The word “language” comes from the fact that we can think of the event E as an “alphabet” and of (finite) sequences of events as “words” (Hopcroft and Ullman 1979). We can further refine such a model by adding statistical information regarding the set of state trajectories (sample paths) of the system. Let us assume that probability distribution functions are available about the “lifetime” of each event type $e \in E$, that is, the elapsed time between successive occurrences of this particular e . A *stochastic timed language* is a timed language together with associated probability distribution functions for the events.

Stochastic timed language modeling is the most detailed in the sense that it contains event information in the form of event occurrences and their orderings, information about the exact times at which the events occur (not only their relative ordering), and statistical information about successive occurrences of events. If we delete the timing information from a timed language, we obtain an *untimed language*, or simply *language*, which is the set of all possible orderings of events that could happen in the given system. For example, the untimed sequence corresponding to the timed sequence of events in Fig. 1 is $\{e_1, e_2, e_3, e_4, e_5\}$.

Untimed and timed languages represent different levels of abstraction at which DES are modeled and studied. The choice of the appropriate level of abstraction clearly depends on the objectives of the analysis. In many instances, we are interested in the “logical behavior” of the system, that is, in ensuring that all the event sequences it can generate satisfy a given set of specifications, e.g., maintaining a precise ordering of events. In this context, the actual timing of events is not required, and it is sufficient to model only the untimed behavior of the system. *Supervisory control* that is discussed in the article ► [Supervisory Control of Discrete-Event Systems](#) is the term established for describing the systematic means (i.e., enabling or disabling events which are controllable) by which the logical behavior of a DES is regulated to achieve

a given specification (Cassandras and Lafortune 2008; Ramadge and Wonham 1987; Moody and Antsaklis 1998).

On the other hand, we may be interested in *event timing* in order to answer questions such as the following: “How much time does the system spend at a particular state?” or “Can this sequence of events be completed by a particular deadline?” More generally, event timing is important in assessing the performance of a DES often measured through quantities such as *throughput* or *response time*. In these instances, we need to consider the timed language model of the system. Since DES frequently operate in a stochastic setting, an additional level of complexity is introduced, necessitating the development of probabilistic models and related analytical methodologies for design and performance analysis based on stochastic timed language models. *Sample path analysis* and *perturbation analysis*, discussed in the entry ► [Perturbation Analysis of Discrete Event Systems](#), refer to the study of sample paths of DES, focusing on the extraction of information for the purpose of efficiently estimating performance sensitivities of the system and, ultimately, achieving online control and optimization (Cassandras and Lafortune 2008; Ho and Cassandras 1983; Ho and Cao 1991; Glasserman 1991).

These different levels of abstraction are complementary, as they address different issues about the behavior of a DES. Although the language-based approach to DES modeling is attractive, it is by itself not convenient to address verification, controller synthesis, or performance issues. This motivates the development of *discrete event modeling formalisms* which represent languages in a manner that highlights structural information about the system behavior and can be used to address analysis and controller synthesis issues. Next, we provide an overview of three major modeling formalisms which are used by most (but not all) system and control theoretic methodologies pertaining to DES. Additional modeling formalisms encountered in the computer science literature include process algebras (Baeten and Weijland 1990) and communicating sequential processes (Hoare 1985).

Automata

A *deterministic automaton*, denoted by G , is a six-tuple

$$G = (\mathcal{X}, \mathcal{E}, f, \Gamma, x_0, \mathcal{X}_m),$$

where $\mathcal{X}$ is the set of *states*, $\mathcal{E}$ is the finite set of *events* associated with the transitions in G , and $f : \mathcal{X} \times \mathcal{E} \rightarrow \mathcal{X}$ is the *transition function*; specifically, $f(x, e) = y$ means that there is a transition labeled by event e from state x to state y and, in general, f is a *partial function* on its domain. $\Gamma : \mathcal{X} \rightarrow 2^{\mathcal{E}}$ is the *active event function* (or feasible event function); $\Gamma(x)$ is the set of all events e for which $f(x, e)$ is defined and it is called the *active event set* (or feasible event set) of G at x . Finally, x_0 is the *initial state* and $\mathcal{X}_m \subseteq \mathcal{X}$ is the set of *marked states*. The terms *state machine* and *generator* (which explains the notation G) are also used to describe the above object. Moreover, if $\mathcal{X}$ is a finite set, we call G a *deterministic finite-state automaton*. A *nondeterministic automaton* is defined by means of a relation over $\mathcal{X} \times \mathcal{E} \times \mathcal{X}$ or, equivalently, a function from $\mathcal{X} \times \mathcal{E}$ to $2^{\mathcal{X}}$.

The automaton G operates as follows. It starts in the initial state x_0 , and upon the occurrence of an event $e \in \Gamma(x_0) \subseteq \mathcal{E}$, it makes a transition to state $f(x_0, e) \in \mathcal{X}$. This process then continues based on the transitions for which f is defined. Note that an event may occur without changing the state, i.e., $f(x, e) = x$. It is also possible that two distinct events occur at a given state causing the exact same transition, i.e., for $a, b \in \mathcal{E}$, $f(x, a) = f(x, b) = y$. What is interesting about the latter fact is that we may not be able to distinguish between events a and b by simply observing a transition from state x to state y .

For the sake of convenience, f is always extended from domain $\mathcal{X} \times \mathcal{E}$ to domain $\mathcal{X} \times \mathcal{E}^*$, where $\mathcal{E}^*$ is the set of *all* finite strings of elements of $\mathcal{E}$, including the empty string (denoted by ε); the $*$ operation is called the *Kleene closure*. This is accomplished in the following recursive manner: $f(x, \varepsilon) := x$ and $f(x, se) := f(f(x, s), e)$ for $s \in \mathcal{E}^*$ and $e \in \mathcal{E}$. The (untimed) language generated by G and

denoted by $\mathcal{L}(G)$ is the set of all strings in $\mathcal{E}^*$ for which the extended function f is defined. The automaton model above is one instance of what is referred to as a *generalized semi-Markov scheme* (GSMS) in the literature of stochastic processes. A GSMS is viewed as the basis for extending automata to incorporate an event timing structure as well as nondeterministic state transition mechanisms, ultimately leading to *stochastic timed automata*, discussed in the sequel.

Let us allow for generally countable sets $\mathcal{X}$ and $\mathcal{E}$ and leave out of the definition any consideration for marked states. Thus, we begin with an automaton model $(\mathcal{X}, \mathcal{E}, f, \Gamma, x_0)$. We extend the modeling setting to *timed automata* by incorporating a “clock structure” associated with the event set $\mathcal{E}$ which now becomes the input from which a specific event sequence can be deduced. The *clock structure* (or *timing structure*) associated with an event set $\mathcal{E}$ is a set $\mathbf{V} = \{\mathbf{v}_i : i \in \mathcal{E}\}$ of clock (or lifetime) sequences

$$\mathbf{v}_i = \{v_{i,1}, v_{i,2}, \dots\}, i \in \mathcal{E}, v_{i,k} \in \mathbb{R}^+, k = 1, 2, \dots$$

M

Timed Automaton. A *timed automaton* is defined as a six-tuple

$$(\mathcal{X}, \mathcal{E}, f, \Gamma, x_0, \mathbf{V}),$$

where $\mathbf{V} = \{\mathbf{v}_i : i \in \mathcal{E}\}$ is a clock structure and $(\mathcal{X}, \mathcal{E}, f, \Gamma, x_0)$ is an automaton. The automaton generates a state sequence $x' = f(x, e')$ driven by an event sequence $\{e_1, e_2, \dots\}$ generated through

$$e' = \arg \min_{i \in \Gamma(x)} \{y_i\} \quad (3)$$

with the clock values $y_i, i \in \mathcal{E}$, defined by

$$y'_i = \begin{cases} y_i - y^* & \text{if } i \neq e' \text{ and } i \in \Gamma(x) \\ v_{i, N_i+1} & \text{if } i = e' \text{ or } i \notin \Gamma(x) \end{cases} \quad i \in \Gamma(x') \quad (4)$$

where the *interevent time* y^* is defined as

$$y^* = \min_{i \in \Gamma(x)} \{y_i\} \quad (5)$$

and the *event scores* $N_i, i \in \mathcal{E}$, are defined by

$$N'_i = \begin{cases} N_i + 1 & \text{if } i = e' \text{ or } i \notin \Gamma(x) \\ N_i & \text{otherwise} \end{cases} \quad i \in \Gamma(x'). \quad (6)$$

In addition, initial conditions are $y_i = v_{i,1}$ and $N_i = 1$ for all $i \in \Gamma(x_0)$. If $i \notin \Gamma(x_0)$, then y_i is undefined and $N_i = 0$.

A simple interpretation of this elaborate definition is as follows. Given that the system is at some state x , the next event e' is the one with the smallest clock value among all feasible events $i \in \Gamma(x)$. The corresponding clock value, y^* , is the interevent time between the occurrence of e and e' , and it provides the amount by which the time, t , moves forward: $t' = t + y^*$. Clock values for all events that remain active in state x' are decremented by y^* , except for the triggering event e' and all newly activated events, which are assigned a new lifetime v_{i,N_i+1} . Event scores are incremented whenever a new lifetime is assigned to them. It is important to note that the “system clock” t is fully controlled by the occurrence of events, which cause it to move forward; if no event occurs, the system remains at the last state observed.

Comparing $x' = f(x, e')$ to the state equation (1) for time-driven systems, we see that the former can be viewed as the event-driven analog of the latter. However, the simplicity of $x' = f(x, e')$ is deceptive: unless an event sequence is given, determining the *triggering* event e' which is required to obtain the next state x' involves the combination of (3)–(6). Therefore, the analog of (1) as a “canonical” state equation for a DES requires all Eqs. (3)–(6). Observe that this timed automaton generates a timed language, thus extending the untimed language generated by the original automaton G .

In the definition above, the clock structure $\mathbf{V}$ is assumed to be fully specified in a deterministic sense and so are state transitions dictated by $x' = f(x, e')$. The sequences $\{\mathbf{v}_i\}, i \in \mathcal{E}$, can be extended to be specified only as stochastic sequences through distribution functions denoted by $F_i, i \in \mathcal{E}$. Thus, the *stochastic clock structure* (or *stochastic timing structure*) associated with an event set $\mathcal{E}$ is a set of distribution functions

$F = \{F_i : i \in \mathcal{E}\}$ characterizing the stochastic clock sequences

$$\{V_{i,k}\} = \{V_{i,1}, V_{i,2}, \dots\}, \quad i \in \mathcal{E}, \\ V_{i,k} \in \mathbb{R}^+, \quad k = 1, 2, \dots$$

It is usually assumed that each clock sequence consists of random variables which are independent and identically distributed (iid) and that all clock sequences are mutually independent. Thus, each $\{V_{i,k}\}$ is completely characterized by a distribution function $F_i(t) = P[V_i \leq t]$. There are, however, several ways in which a clock structure can be extended to include situations where elements of a sequence $\{V_{i,k}\}$ are correlated or two clock sequences are interdependent. As for state transitions which may be nondeterministic in nature, such behavior is modeled through state transition probabilities as explained next.

Stochastic Timed Automaton. We can extend the definition of a timed automaton by viewing the state, event, and all event scores and clock values as random variables denoted respectively by capital letters X, E, N_i , and $Y_i, i \in \mathcal{E}$. Thus, a *stochastic timed automaton* is a six-tuple

$$(\mathcal{X}, \mathcal{E}, \Gamma, p, p_0, F),$$

where $\mathcal{X}$ is a countable *state space*; $\mathcal{E}$ is a countable *event set*; $\Gamma(x)$ is the *active event set* (or feasible event set); $p(x'; x, e')$ is a *state transition probability* defined for all $x, x' \in \mathcal{X}, e' \in \mathcal{E}$ and such that $p(x'; x, e') = 0$ for all $e' \notin \Gamma(x)$; p_0 is the probability mass function $P[X_0 = x], x \in \mathcal{X}$, of the initial state X_0 ; and F is a *stochastic clock structure*. The automaton generates a stochastic state sequence $\{X_0, X_1, \dots\}$ through a transition mechanism (based on observations $X = x, E' = e'$):

$$X' = x' \text{ with probability } p(x'; x, e') \quad (7)$$

and it is driven by a stochastic event sequence $\{E_1, E_2, \dots\}$ generated exactly as in (3)–(6) with random variables E, Y_i , and $N_i, i \in \mathcal{E}$, instead of deterministic quantities and with $\{V_{i,k}\} \sim$

F_i ($\sim$ denotes “with distribution”). In addition, initial conditions are $X_0 \sim p_0(x)$, $Y_i = V_{i,1}$, and $N_i = 1$ if $i \in \Gamma(X_0)$. If $i \notin \Gamma(X_0)$, then Y_i is undefined and $N_i = 0$.

It is conceivable for two events to occur at the same time, in which case we need a priority scheme to overcome a possible ambiguity in the selection of the triggering event in (3). In practice, it is common to expect that every F_i in the clock structure is absolutely continuous over $[0, \infty)$ (so that its density function exists) and has a finite mean. This implies that two events can occur at exactly the same time only with probability 0.

A stochastic process $\{X(t)\}$ with state space $\mathcal{X}$ which is generated by a stochastic timed automaton $(\mathcal{X}, \mathcal{E}, \Gamma, p, p_0, F)$ is referred to as a *generalized semi-Markov process* (GSMP). This process is used as the basis of much of the sample path analysis methods for DES (see Cassandras and LaFortune 2008; Ho and Cao 1991; Glasserman 1991).

Petri Nets

An alternative modeling formalism for DES is provided by *Petri nets*, originating in the work of C. A. Petri in the early 1960s. Like an automaton, a Petri net (Peterson 1981) is a device that manipulates events according to certain rules. One of its features is the inclusion of explicit conditions under which an event can be enabled. The Petri net modeling framework is the subject of the article ► [Modeling, Analysis, and Control with Petri Nets](#). Thus, we limit ourselves here to a brief introduction. First, we define a Petri net graph, also called the *Petri net structure*. Then, we adjoin to this graph an initial state, a set of marked states, and a transition labeling function, resulting in the complete Petri net model, its associated dynamics, and the languages that it generates and marks.

Petri Net Graph. A Petri net is a directed *bipartite graph* with two types of nodes, *places* and *transitions*, and arcs connecting them. Events are associated with transition nodes. In order

for a transition to occur, several conditions may have to be satisfied. Information related to these conditions is contained in place nodes. Some such places are viewed as the “input” to a transition; they are associated with the conditions required for this transition to occur. Other places are viewed as the output of a transition; they are associated with conditions that are affected by the occurrence of this transition. A *Petri net graph* is formally defined as a weighted directed bipartite graph (P, T, A, w) where P is the finite set of *places* (one type of node in the graph), T is the finite set of *transitions* (the other type of node in the graph), $A \subseteq (P \times T) \cup (T \times P)$ is the set of arcs with directions from places to transitions and from transitions to places in the graph, and $w : A \rightarrow \{1, 2, 3, \dots\}$ is the *weight function* on the arcs. Let $P = \{p_1, p_2, \dots, p_n\}$, and $T = \{t_1, t_2, \dots, t_m\}$. It is convenient to use $I(t_j)$ to represent the set of input places to transition t_j . Similarly, $O(t_j)$ represents the set of output places from transition t_j . Thus, we have $I(t_j) = \{p_i \in P : (p_i, t_j) \in A\}$ and $O(t_j) = \{p_i \in P : (t_j, p_i) \in A\}$.

Petri Net Dynamics. *Tokens* are assigned to places in a Petri net graph in order to indicate the fact that the condition described by that place is satisfied. The way in which tokens are assigned to a Petri net graph defines a *marking*. Formally, a *marking* x of a Petri net graph (P, T, A, w) is a function $x : P \rightarrow \mathbb{N} = \{0, 1, 2, \dots\}$. Marking x defines row vector $\mathbf{x} = [x(p_1), x(p_2), \dots, x(p_n)]$, where n is the number of places in the Petri net. The i th entry of this vector indicates the (nonnegative integer) number of tokens in place p_i , $x(p_i) \in \mathbb{N}$. In Petri net graphs, a token is indicated by a dark dot positioned in the appropriate place. The *state* of a Petri net is defined to be its marking vector $\mathbf{x}$. The state transition mechanism of a Petri net is captured by the structure of its graph and by “moving” tokens from one place to another. A transition $t_j \in T$ in a Petri net is said to be *enabled* if

$$x(p_i) \geq w(p_i, t_j) \text{ for all } p_i \in I(t_j). \quad (8)$$

In words, transition t_j in the Petri net is enabled when the number of tokens in p_i is at least as large as the weight of the arc connecting p_i to t_j , for all places p_i that are input to transition t_j . When a transition is enabled, it can occur or *fire*. The *state transition function* of a Petri net is defined through the change in the state of the Petri net due to the firing of an enabled transition. The state transition function, $f : \mathbb{N}^n \times T \rightarrow \mathbb{N}^n$, of Petri net (P, T, A, w, x) is defined for transition $t_j \in T$ if and only if (8) holds. Then, we set $\mathbf{x}' = f(\mathbf{x}, t_j)$ where

$$\begin{aligned} x'(p_i) &= x(p_i) - w(p_i, t_j) + w(t_j, p_i), \\ i &= 1, \dots, n. \end{aligned} \quad (9)$$

An “enabled transition” is therefore equivalent to a “feasible event” in an automaton. But whereas in automata the state transition function enumerates all feasible state transitions, here the state transition function is based on the structure of the Petri net. Thus, the next state defined by (9) explicitly depends on the input and output places of a transition and on the weights of the arcs connecting these places to the transition. According to (9), if p_i is an input place of t_j , it loses as many tokens as the weight of the arc from p_i to t_j ; if it is an output place of t_j , it gains as many tokens as the weight of the arc from t_j to p_i . Clearly, it is possible that p_i is both an input and output place of t_j .

In general, it is entirely possible that, after several transition firings, the resulting state is $\mathbf{x} = [0, \dots, 0]$ or that the number of tokens in one or more places grows arbitrarily large after an arbitrarily large number of transition firings. The latter phenomenon is a key difference with automata, where finite-state automata have only a finite number of states, by definition. In contrast, a finite Petri net graph may result in a Petri net with an unbounded number of states. It should be noted that a finite-state automaton can always be represented as a Petri net; on the other hand, not all Petri nets can be represented as finite-state automata.

Similar to timed automata, we can define *timed Petri nets* by introducing a clock structure, except that now a clock sequence $\mathbf{v}_j$ is associated

with a transition t_j . A positive real number, $v_{j,k}$, assigned to t_j has the following meaning: when transition t_j is enabled for the k th time, it does not fire immediately, but incurs a firing delay given by $v_{j,k}$; during this delay, tokens are kept in the input places of t_j . Not all transitions are required to have firing delays. Thus, we partition T into subsets T_0 and T_D , such that $T = T_0 \cup T_D$. T_0 is the set of transitions always incurring zero firing delay, and T_D is the set of transitions that generally incur some firing delay. The latter are called *timed transitions*. The *clock structure* (or *timing structure*) associated with a set of timed transitions $T_D \subseteq T$ of a marked Petri net (P, T, A, w, x) is a set $\mathbf{V} = \{\mathbf{v}_j : t_j \in T_D\}$ of clock (or lifetime) sequences $\mathbf{v}_j = \{v_{j,1}, v_{j,2}, \dots\}$, $t_j \in T_D$, $v_{j,k} \in \mathbb{R}^+$, $k = 1, 2, \dots$. A *timed Petri net* is a six-tuple $(P, T, A, w, x, \mathbf{V})$, where (P, T, A, w, x) is a marked Petri net and $\mathbf{V} = \{\mathbf{v}_j : t_j \in T_D\}$ is a clock structure. It is worth mentioning that this general structure allows for a variety of behaviors in a timed Petri net, including the possibility of multiple transitions being enabled at the same time or an enabled transition being preempted by the firing of another, depending on the values of the associated firing delays. The need to analyze and control such behavior in DES has motivated the development of a considerable body of analysis techniques for Petri net models which have been proven to be particularly suitable for this purpose (Peterson 1981; Moody and Antsaklis 1998).

Dioid Algebras

Another modeling framework is based on developing an algebra using two operations: $\min\{a, b\}$ (or $\max\{a, b\}$) for any real numbers a and b and addition $(a + b)$. The motivation comes from the observation that the operations “min” and “+” are the only ones required to develop the timed automaton model. Similarly, the operations “max” and “+” are the only ones used in developing the timed Petri net models described above. The operations are formally named *addition* and *multiplication* and denoted by $\oplus$ and $\otimes$ respectively. However, their actual meaning (in

terms of regular algebra) is different. For any two real numbers a and b , we define

$$\text{Addition : } a \oplus b \equiv \max\{a, b\} \quad (10)$$

$$\text{Multiplication : } a \otimes b \equiv a + b. \quad (11)$$

This dioid algebra is also called a $(\max, +)$ algebra (Cuninghame-Green 1979; Baccelli et al. 1992). If we consider a standard linear discrete time system, its state equation is of the form

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) + \mathbf{B}\mathbf{u}(k),$$

which involves (regular) multiplication ($\times$) and addition ($+$). It turns out that we can use a $(\max, +)$ algebra with DES, replacing the $(+, \times)$ algebra of conventional time-driven systems, and come up with a representation similar to the one above, thus paralleling to a considerable extent the analysis of classical time-driven linear systems. We should emphasize, however, that this particular representation is only possible for a subset of DES. Moreover, while conceptually this offers an attractive way to capture the event timing dynamics in a DES, from a computational standpoint, one still has to confront the complexity of performing the “max” operation when numerical information is ultimately needed to analyze the system or to design controllers for its proper operation.

Control and Optimization of Discrete Event Systems

The various control and optimization methodologies developed to date for DES depend on the modeling level appropriate for the problem of interest.

Logical Behavior. Issues such as ordering events according to some specification or ensuring the reachability of a particular state are normally addressed through the use of automata and Petri nets (Ramadge and Wonham 1987; Chen and Lafortune 1991; Moody and Antsaklis 1998). Supervisory control theory provides a systematic framework for formulating and

solving problems of this type; a comprehensive coverage can be found in Cassandras and Lafortune (2008). Logical behavior issues are also encountered in the *diagnosis* of partially observed DES, a topic covered in the article [► Diagnosis of Discrete Event Systems](#).

Event Timing. When timing issues are introduced, timed automata and timed Petri nets are invoked for modeling purposes. Supervisory control in this case becomes significantly more complicated. An important class of problems, however, does not involve the ordering of individual events, but rather the requirement that selected events occur within a given “time window” or with some desired periodic characteristics. Models based on the algebraic structure of timed Petri nets or the $(\max, +)$ algebra provide convenient settings for formulating and solving such problems (Baccelli et al. 1992; Glasserman and Yao 1994).

Performance Analysis. As in classical control theory, one can define a performance (or cost) function as a means for quantifying system behavior. This approach is particularly crucial in the study of stochastic DES. Because of the complexity of DES dynamics, analytical expressions for such performance metrics in terms of controllable variables are seldom available. This has motivated the use of simulation and, more generally, the study of DES sample paths; these have proven to contain a surprising wealth of information for control purposes. The theory of *perturbation analysis* presented in the article [► Perturbation Analysis of Discrete Event Systems](#) has provided a systematic way of estimating performance sensitivities with respect to system parameters (Cassandras and Lafortune 2008; Ho and Cao 1991; Glasserman 1991; Cassandras and Panayiotou 1999).

Discrete Event Simulation. Because of the aforementioned complexity of DES dynamics, simulation becomes an essential part of DES performance analysis (Law and Kelton 1991). Discrete event simulation can be defined as a systematic way of generating sample paths of a DES by means of a timed automaton or its

stochastic counterpart. The same process can be carried out using a Petri net model or one based on the dioid algebra setting.

Optimization. Optimization problems can be formulated in the context of both untimed and timed models of DES. Moreover, such problems can be formulated in both a deterministic and a stochastic setting. In the latter case, the ability to efficiently estimate performance sensitivities with respect to controllable system parameters provides a powerful tool for stochastic gradient-based optimization (when one can define derivatives) (Vázquez-Abad et al. 1998).

A treatment of all such problems from an application-oriented standpoint, along with further details on the use of the modeling frameworks discussed in this entry, can be found in the article ► [Applications of Discrete Event Systems](#).

Monotone Systems in Biology

David Angeli

Department of Electrical and Electronic Engineering, Imperial College London, London, UK

Dipartimento di Ingegneria dell'Informazione, University of Florence, Florence, Italy

Abstract

Mathematical models arising in biology might sometime exhibit the remarkable feature of preserving ordering of their solutions with

respect to initial data: in words, the “more” of x (the state variable) at time 0, the more of it at all subsequent times. Similar monotonicity properties are possibly exhibited also with respect to input levels. When this is the case, important features of the system’s dynamics can be inferred on the basis of purely qualitative or relatively basic quantitative knowledge of the system’s characteristics. We will discuss how monotonicity-related tools can be used to analyze and design biological systems with prescribed dynamical behaviors such as global stability, multistability, or periodic oscillations.

Keywords

Monotone systems · Systems biology · Synthetic biology · Convergence and stability · Biological networks · Multistability

Introduction

Ordinary differential equations of a scalar unknown, under suitable assumptions for unicity of solutions, trivially enjoy the property that any pair of ordered initial conditions (according to the standard $\leq$ order defined for real numbers) gives rise to ordered solutions at all positive times (as well as negative, though this is less relevant for the developments that follow). Monotone systems are a special but significant class of dynamical models, possibly evolving in high-dimensional or even infinite-dimensional state spaces that are nevertheless characterized by a similar property holding with respect to a suitably defined notion of partial order. They became the focus of considerable interest in mathematics after a series of seminal papers by Hirsch (1985, 1988) provided the basic definitions as well as deep results showing how generic convergence properties of their solutions are expected under suitable technical assumptions. Shortly before that, (Smale 1976), Smale’s construction had already highlighted

how specific solutions could instead exhibit arbitrary behavior (including periodic or chaotic). Further results along these lines provide insight into which set of extra assumptions allow one to strengthen generic convergence to global convergence, including existence of positive first integrals (Mierczynski 1987; Banaji and Angeli 2010), tridiagonal structure (Smillie 1984), or positive translation invariance (Angeli and Sontag 2008a).

While these tools were initially developed having in mind applications arising in ecology, epidemiology, chemistry, or economy, it was due to the increased importance of mathematical modeling in molecular biology and the subsequent rapid development of systems biology as an emerging independent field of investigation that they became particularly relevant to biology. The entry Angeli and Sontag (2003) first introduced the notion of control monotone systems, including input and output variables, that is of interest if one is looking at systems arising from interconnection of monotone modules. Small-gain theorems and related conditions were defined to study both positive (Angeli and Sontag 2004b) and negative (Angeli and Sontag 2003) feedback interconnections by relating their asymptotic behavior to properties of the discrete iterations of a suitable map, called the steady-state characteristic of the system.

In particular, convergence of this map is related to convergent solutions for the original continuous time system; on the other hand, specific negative feedback interconnections can instead give rise to oscillations as a result of Hopf’s bifurcations as in Angeli and Sontag (2008b) or to relaxation oscillators as highlighted in Gedeon and Sontag (2007).

A parallel line of investigation, originated in the work of Volpert et al. (1994), exploited the specific features of models arising in biochemistry by focusing on structural conditions for monotonicity of chemical reaction networks (Angeli et al. 2010; Banaji 2009). Monotonicity is only one of the possible tools adopted in the study of dynamics for such class of models in the related field of chemical reaction network theory.

Mathematical Preliminaries

To illustrate the main tools of monotone dynamics, we consider in the following systems defined on partially ordered input, state, and output spaces. Namely, along with the sets U , X , and Y (which denote input, state, and output space, respectively), we consider corresponding partial orders $\succeq_X, \succeq_U, \succeq_Y$. A typical way of defining a partial order on a set S embedded in some Euclidean space E , $S \subset E$, is to first identify a cone K of positive vectors which belong to E . A cone in this context is any closed convex set which is preserved under multiplication times nonnegative scalars and such that $K \cap -K = \{0\}$. Accordingly we may denote $s_1 \succeq_S s_2$ whenever $s_1 - s_2 \in K$. A typical choice of K in the case of finite dimensional $E = \mathbb{R}^n$ is the positive orthant, ($K = [0, +\infty)^n$), in which case $\succeq$ can be interpreted as componentwise inequalities. More general orthants are also very useful in several applications as well as more exotic cones, smooth or polyhedral, according to the specific model considered. When dealing with input signals, we let $\mathcal{U}$ denote the set of locally essentially bounded and measurable functions of time. In particular, we inherit a partial order on $\mathcal{U}$ from the partial order on U according to the following definition

$$u_1(\cdot) \succeq_{\mathcal{U}} u_2(\cdot) \Leftrightarrow u_1(t) \succeq_U u_2(t) \quad \forall t \in \mathbb{R}.$$

When obvious from the context, we do not emphasize the space to which variables belong and simply write $\succeq$. Strict order notions are also of interest and specially relevant for some of the deepest implications of the theory. We let $s_1 \succ s_2$ denote $s_1 \succeq s_2$ and $s_1 \neq s_2$. While for partial orders induced by positivity cones, we let $s_1 \gg s_2$ denote $s_1 - s_2 \in \text{int}(K)$.

A dynamical system is for us a continuous map $\varphi : \mathbb{R} \times X \rightarrow X$ which fulfills the property, $\varphi(0, x) = x$ for all $x \in X$ and $\varphi(t_2, \varphi(t_1, x)) = \varphi(t_1 + t_2, x)$ for all $t_1, t_2 \in \mathbb{R}$. Sometimes, when solutions are not globally defined (for instance, if the system is defined through a set of nonlinear differential equations), it is enough to restrict the

definitions that follow to the domain of existence of solutions.

Definition 1 A monotone system φ is one that fulfills the following:

$$\begin{aligned} \forall x_1, x_2 \in X : x_1 \succeq x_2 \\ \varphi(t, x_1) \succeq \varphi(t, x_2) \quad \forall t \geq 0. \end{aligned} \quad (1)$$

A system φ is strongly monotone when the following holds:

$$\begin{aligned} \forall x_1, x_2 \in X : x_1 \succ x_2 \\ \varphi(t, x_1) \gg \varphi(t, x_2) \quad \forall t > 0. \end{aligned} \quad (2)$$

A control system is characterized by two continuous mappings, $\varphi : \mathbb{R} \times X \times \mathcal{U} \rightarrow X$ and the readout map $h : X \times U \rightarrow Y$.

Definition 2 A control system is monotone if:

$$\begin{aligned} \forall u_1, u_2 \in \mathcal{U} : u_1 \succeq u_2, \\ \forall x_1, x_2 \in X : x_1 \succeq x_2, \quad \forall t \geq 0 \\ \varphi(t, x_1, u_1) \succeq \varphi(t, x_2, u_2) \end{aligned} \quad (3)$$

and:

$$\begin{aligned} \forall u_1, u_2 \in U : u_1 \succeq u_2, \\ \forall x_1, x_2 \in X : x_1 \succeq x_2, \\ h(x_1, u_1) \succeq h(x_2, u_2). \end{aligned} \quad (4)$$

Notice that for any ordered state and input pairs x_1, x_2, u_1, u_2 , the signals y_1 and y_2 defined as $y_1(t) := h(\varphi(t, x_1, u_1), u_1(t))$, $y_2(t) := h(\varphi(t, x_2, u_2), u_2(t))$ also fulfill, thanks to the Definition 2, $y_1(t) \succeq_Y y_2(t)$ (for all $t \geq 0$).

A system which is monotone with respect to the positive orthant is called cooperative. If a system is cooperative after reverting the direction of time, it is called competitive. Checking if a mathematical model specified by differential equations is monotone with respect to the partial order induced by some cone K is not too difficult. In particular, monotonicity, in its most basic formulation (1), simply amounts to a check of positive invariance of the set $\Gamma := \{(x_1, x_2) \in X^2 : x_1 \succeq x_2\}$ for a system formed by two copies of φ in parallel. This can be assessed without

explicit knowledge of solutions, for instance, by using the notion of tangent cones and Nagumo's Theorem (Angeli and Sontag 2003). Sufficient conditions also exist to assess strong monotonicity, for instance, in the case of orthant cones. Finding whether there exists an order (as induced, for instance, by a suitable cone K) which can make a system monotone is instead a harder task which normally entails a good deal of insight in the systems dynamics.

It is worth mentioning that for the special case of linear systems, monotonicity is just equivalent to invariance of the cone K , as incremental properties (referred to pairs of solutions) are just equivalent to their non-incremental counterparts (referred to the 0 solution). In this respect, a substantial amount of theory exists starting from classical works such as the Perron-Frobenius theory on positive and cone-preserving maps; this is however outside the scope of this entry; the interested reader may refer to Farina and Rinaldi (2000) for a recent book on the subject.

Monotone Dynamics

We divide this section in three parts; first we summarize the main tools for checking monotonicity with respect to orthant cones, then we recall some of the main consequences of monotonicity for the long-term behavior of solutions, and, finally, we study interconnections of monotone systems.

Checking Monotonicity

Orthant cones and the partial orders they induce play a major role in biology applications. In fact, for systems described by equations

$$\dot{x} = f(x) \quad (5)$$

with $X \subset \mathbb{R}^n$ open and $f : X \rightarrow \mathbb{R}^n$ of class $\mathcal{C}^1$, the following characterization holds:

Proposition 1 *The system φ induced by the set of differential equations (5) is cooperative if and only if the Jacobian $\frac{\partial f}{\partial x}$ is a Metzler matrix for all $x \in X$.*

We recall that M is Metzler if $m_{ij} \geq 0$ for all $i \neq j$. Let $\Lambda = \text{diag}[\lambda_1, \dots, \lambda_n]$ with $\lambda_i \in \{-1, 1\}$ and assume that the orthant $\mathcal{O} = \Lambda[0, +\infty)^n$. It is straightforward to see

that $x_1 \succeq_{\mathcal{O}} x_2 \Leftrightarrow \Lambda x_1 \geq \Lambda x_2$, where $\geq$ denotes the partial order induced by the positive orthant, while $\succeq_{\mathcal{O}}$ denotes the order induced by $\mathcal{O}$. This means that we may check monotonicity with respect to $\mathcal{O}$ by performing a simple change of coordinates $z = \Lambda x$. As a corollary:

Proposition 2 *The system φ induced by the set of differential equations (5) is monotone with respect to $\succeq_{\mathcal{O}}$ if and only if $\Lambda \frac{\partial f}{\partial x} \Lambda$ is a Metzler matrix for all $x \in X$.*

Notice that conditions of Propositions 1 and 2 can be expressed in terms of sign constraints on off-diagonal entries of the Jacobian; in biological terms a sign constraint in an off-diagonal entry amounts to asking that a particular species (meaning chemical compound or otherwise) consistently exhibit throughout the considered model's state space either an excitatory or inhibitory effect on some other species of interest. Qualitative diagrams showing effects of species on each other are commonly used by biologists to understand the working principles of biomolecular networks.

Remarkably, Proposition 2 has also an interesting graph theoretical interpretation if one thinks of $\text{sign}\left(\frac{\partial f}{\partial x}\right)$ as the adjacency matrix of a graph with nodes $x_1 \dots x_n$ corresponding to the state variables of the system.

Proposition 3 *The system φ induced by the set of differential equations (5) is monotone with respect to $\succeq_{\mathcal{O}}$ if and only if the directed graph of adjacency matrix $\text{sign}\left(\frac{\partial f}{\partial x}\right)$ (neglecting diagonal entries) has undirected loops with an even number of negative edges.*

This means in particular that $\frac{\partial f}{\partial x}$ must be sign-symmetric (no predator-prey-type interactions) and in addition that a similar parity property has to hold on undirected loops of arbitrary length. Sufficient conditions for strong monotonicity are also known, for instance, in terms of irreducibility of the Jacobian matrix (Kamke's condition; see Hirsch and Smith 2003).

Asymptotic Dynamics

As previously mentioned, several important implications of monotonicity are with respect

to asymptotic dynamics. Let $\mathcal{E}$ denote the set of equilibria of φ . The following result is due to Hirsch (1985).

Theorem 1 *Let φ be a strongly monotone system with bounded solutions. There exists a zero measure set Q such that each solution starting in $X \setminus Q$ converges toward $\mathcal{E}$.*

Global convergence results can be achieved for important classes of monotone dynamics. For instance, when increasing conservation laws are present, see Banaji and Angeli (2010):

Theorem 2 *Let $X \subset K \subset \mathbb{R}^n$ be any two proper cones. Let φ on X be strongly monotone with respect to the partial order induced by K and preserving a K -increasing first integral. Then every bounded solution converges.*

Dually to first integrals, positive translation invariance of the dynamics also provides grounds for global convergence (see Angeli and Sontag 2008a):

Theorem 3 *If a system is strongly monotone and fulfills $\varphi(t, x_0 + hv) = \varphi(t, x_0) + hv$ for all $h \in \mathbb{R}$ and some $v \gg 0$, then all solutions with bounded projections in $v^\perp$ converge.*

The class of tridiagonal cooperative systems has also been investigated as a significant remarkable class of global convergent dynamics (see Smillie 1984). These arise from differential equations $\dot{x} = f(x)$ when $\partial f_i / \partial x_j = 0$ for all $|i - j| > 1$.

Finally it is worth emphasizing how significant for biological systems, often subject to phenomena evolving at different time scales, are also results on singular perturbations (Wang and Sontag 2008; Gedeon and Sontag 2007) and on monotonicity (with respect to time) of transient responses, as highlighted in Angeli and Sontag (2004a) and applied in Ascensao et al. (2016).

Interconnected Monotone Systems

Results on interconnected monotone SISO systems are surveyed in Angeli and Sontag (2004a). The main tool used in this context is the notion of input-state and input-output steady-state characteristic.

Definition 3 A control system admits a well-defined input-state characteristic if for all constant inputs u there exists a unique globally asymptotically stable equilibrium $k_x(u)$ and the map $k_x(u)$ is continuous. If moreover the equilibrium is hyperbolic, then k_x is called a nondegenerate characteristic. The input-output characteristic is defined as $k_y(u) = h(k_x(u))$.

Let φ be system with a well-defined input-output characteristic k_y ; we may define the iteration:

$$u_{k+1} = k_y(u_k). \quad (6)$$

It is clear that fixed points of (6) correspond to input values (and therefore to equilibria through the characteristic map k_x) of the closed-loop system derived by considering the unity feedback interconnection $u = y$. What is remarkable for monotone systems is that both in the case of positive and negative feedback and in a precise sense, stability properties of the fixed points of the discrete iteration (6) are matched by stability properties of the corresponding associated solutions of the original continuous time system. See Angeli and Sontag (2004b) for the case of positive feedback interconnections and Angeli et al. (2004) for applications of such results to synthesis and detection of multistability in molecular biology.

Multistability, in particular, is an important dynamical feature of specific cellular systems and can be achieved, with good degree of robustness with respect to different types of uncertainties, by means of positive feedback interconnections of monotone subsystems. The typical input-output characteristic k_y giving rise to such behavior is, in the SISO case, that of a sigmoidal function intersecting in 3 points the diagonal $u = y$. Two of the fixed points, namely, u_1 and u_3 (see Fig. 1), are asymptotically stable for (6), and the corresponding equilibria of the original continuous time monotone system are also asymptotically stable with a basin of attraction which covers almost all initial conditions. The fixed point u_2 is unstable and the corresponding equilibrium is also such (under suitable technical assumption on the non-degeneracy of the I-O characteristic). Extensions of similar criteria to the MIMO case are presented in Enciso and Sontag (2005). See

Monotone Systems in Biology, Fig. 1 Fixed points of a sigmoidal Input-Output characteristic

Monotone Systems in Biology, Fig. 2 Fixed point of a decreasing Input-Output characteristic

Sootla et al. (2016) for pulse design techniques finalized to driving a bistable monotone system toward a specific equilibrium state. Another recent application of bistability and monotone systems theory is quorum sensing as described in Nikolaev and Sontag (2016).

Negative feedback normally destroys monotonicity. As a result, likelihood of complex dynamical behavior is highly increased. Nevertheless, input-output characteristics still can provide useful insight in the system's dynamics at least in the case of low feedback gain or for high feedback gains in the presence of sufficiently large delays. For instance, unity negative feedback interconnection of a SISO monotone system may give rise to a unique and globally asymptotically stable fixed point of (6), thanks to the decreasingness of the input-output characteristic and as shown in Fig. 2. Under such circumstances a small-gain result applies, and global asymptotic stability of the corresponding equilibrium is guaranteed regardless of arbitrary input delays in the systems. See Angeli and Sontag (2003) for the simplest small-gain theorem developed in the context of SISO negative feedback interconnections of monotone systems and Enciso and Sontag (2006) for generalizations

to systems with multiple inputs as well as delays. A generalization of small-gain results to the case of MIMO systems which are neither in a positive nor negative feedback configuration is presented in Angeli and Sontag (2011).

When the iteration (6) has an unstable fixed point, for instance, it converges to a period-2 solution; one may expect insurgence of oscillations around the equilibrium through a Hopf's bifurcation provided sufficiently large delays in the input channels are allowed. This situation is analyzed in Angeli and Sontag (2008b) and illustrated through the study of the classical Golbeter's model for the *Drosophila*'s circadian rhythm. A related approach was recently proposed in Blanchini et al. (2015), where structural conditions for oscillations and multistationarity are studied by investigating the sign of feedback loops arising from the interconnection of monotone systems.

Summary and Future Directions

Verifying that a control system preserves some ordering of initial conditions provides important and far-reaching implications for its dynamics. Insurgence of specific behaviors can often

be inferred on the basis of purely qualitative knowledge (as in the case of the Hirsch's generic convergence theorem) as well as additional basic quantitative knowledge as in the case of positive and negative feedback interconnections of monotone systems. For the above reasons, applications in molecular biology of monotone system's theory are gradually emerging: for instance, in the study of MAPK cascades or circadian oscillations, as well as in chemical reaction network theory. Generally speaking, while monotonicity as a whole cannot be expected in large networks, experimental data shows that the number of negative feedback loops in biological regulatory networks is significantly lower than in a random signed graph of comparable size (Maayan et al. 2008).

Analyzing the properties of monotone dynamics may potentially lead to better understanding of the key regulatory mechanisms of complex networks as well as the development of bottom-up approaches for identification of meaningful submodules in biological networks. Potential research directions may include both novel computational tools as well as specific applications to systems biology, for instance:

- algorithms for detection of monotonicity with respect to exotic orders (such as arbitrary polytopic cones or even state-dependent cones);
- application of monotonicity-based ideas to control synthesis (see, for instance, Aswani and Tomlin (2009) where the special class of piecewise affine systems is considered);

Motion Description Languages and Symbolic Control

Sean B. Andersson

Mechanical Engineering and Division of Systems Engineering, Boston University, Boston, MA, USA

Abstract

The fundamental idea behind symbolic control is to mitigate the complexity of a dynamic system by limiting the set of available controls to a typically finite collection of symbols. Each symbol represents a control law that may be either open- or closed-loop. With these symbols, a simpler description of the motion of the system can be created, thereby easing the challenges of analysis and control design. In this entry, we provide a high-level description of symbolic control; discuss briefly its history, connections, and applications; and provide a few insights into where the field is going.

Keywords

Abstraction · Complex systems · Formal methods

Introduction

Systems and control theory is a powerful paradigm for analyzing, understanding, and controlling dynamic systems. Traditional tools in the field for developing and analyzing control laws, however, face significant challenges when one needs to deal with the complexity that arises in many practical, real-world settings such as the control of autonomous, mobile systems operating in uncertain, and changing physical environments. This is particularly true when the tasks to be achieved are not easily framed in terms of motion to a point in the state space. One of the primary goals of symbolic control is to mitigate this complexity by abstracting some combination of the system dynamics, the space

of control inputs, and the physical environment to a simpler, typically finite, model.

This fundamental idea, namely, that of abstracting away the complexity of the underlying dynamics and environment, is in fact a quite natural one. Consider, for example, how you give instructions to another person wanting to go to a point of interest. It would be absurd to provide details at the level of their actuators, namely, with commands to their individual muscles (or, to carry the example to an even more absurd extreme, to the dynamic components that make up those muscles). Rather, very high-level commands are given, such as “follow the road,” “turn right,” and so on. Each of these provides a description of what to do with the understanding that the person can carry out those commands in their own fashion. Similarly, the environment itself is abstracted, and only elements meaningful to the task at hand are described. Thus, continuing the example above, rather than providing metric information or a detailed map, the instructions may use environmental features to determine when particular actions should be terminated, and the next begun, such as “follow the road until the second intersection, then turn right.”

Underlying the idea of symbolic control is the notion that rich behaviors can result from simple actions. This premise was used in many early robots and can be traced back at least to the ideas of Norbert Wiener on cybernetics (see Arkin 1998). It is at the heart of the behavior-based approach to robotics (Brooks 1986). Similar ideas can also be seen in the development of a high-level language (G-codes) for computer numerically controlled (CNC) machines. The key technical ideas in the more general setting of symbolic control for dynamic systems can be traced back to Brockett (1988) which introduced ideas of formalizing a modular approach to programming motion control devices through the development of a motion description language (MDL).

The goal of the present work is to introduce the interested reader to the general ideas of symbolic control as well as to some of its application areas and research directions. While it is not a survey paper, a few select references are provided

throughout to point the reader in hopefully fruitful directions into the literature.

Models and Approaches

There are at least two related but distinct approaches to symbolic control. Both begin with a mathematical description of the system, typically given as an ordinary differential equation of the form

$$\dot{x} = f(x, u, t), \quad y = h(x, t) \quad (1)$$

where x is a vector describing the state of the system, y is the output of the sensors of the system, and u is the control input.

Under the first approach to symbolic control, the focus is on reducing the complexity of the space of possible control signals by limiting the system to a typically finite collection of control symbols. Each of these symbols represents a control law that may be open loop or may utilize output feedback. For example, *Follow the road* could be a feedback control law that uses sensor measurements to determine the position relative to the road and then applies steering commands so that the system stays on the road while simultaneously maintaining a constant speed. There are, of course, many ways to accomplish the specifics of this task, and the details will depend on the particular system. Thus, an autonomous four-wheeled vehicle equipped with a laser rangefinder, an autonomous motorcycle equipped with ultrasonic sensors, or an autonomous aerial vehicle with a camera would each carry out the command in their own way, and each would have very different trajectories. They would all, however, satisfy the notion of *Follow the road*. Description of the behavior of the system can then be given in terms of the abstract symbols rather than in terms of the details of the trajectories.

Typically, each of these symbols describes an action that at least conceptually is simple. In order to generate rich motions to carry out complex tasks, the system is switched between the available symbols. Switching conditions are often referred to as *interrupts*. Interrupts may be

purely time based (e.g., apply a given symbol for T seconds) or may be expressed in terms of symbols representing certain environmental conditions. These may be simple function of the measurements (e.g., interrupt when an intersection is detected) or may represent more complicated scenarios with history and dynamics (e.g., interrupt after the second intersection is detected). Just as the input symbols abstract away the details of the control space and of the motion of the system, the interrupt symbols abstract away the details of the environment. For example, *intersection* has a clear high-level meaning but a very different sensor “signature” for particular systems.

As a simple illustrative example, consider a collection of control symbols designed for moving along a system of roads, {*Follow road*, *Turn right*, *Turn left*} and a collection of interrupt symbols for triggering changes in such a setting {*In intersection*, *Clear of intersection*}. Suppose there are two vehicles that can each interpret these symbols, an autonomous car and a snake-like robot, as illustrated in Fig. 1. It is reasonable to assume that the control symbols each describe relatively complex dynamics that allow, for example, for obstacle avoidance while carrying out the action. Figure 1 illustrates a possible situation where the two systems carry out the plan defined by the symbolic sequence

(*Follow the road UNTIL In intersection*)
(*Turn right UNTIL Clear of intersection*)

The intent of this plan is for the system to navigate a right-hand turn. As shown in the figure, the actual trajectories followed by the systems can be markedly different due in part to system dynamics (the snakelike robot undulates while the car does not) as well as to different sensor responses (when the car goes through, there is a parked vehicle that it must navigate around while the snakelike robot found a clear path during its execution). Despite these differences, both systems achieve the goal of the plan.

The collection of control and interrupt symbols can be thought of as a language for describing and specifying motion and are used to write programs that can be compiled into an executable for a specific system. Different rules for doing this can be established that define different languages, analogous to different high-level programming languages such as C++, Java, or Python. Further details can be found in, for example, Manikonda et al. (1998).

Under the second approach, the focus is on representing the dynamics and state space (or environment) of the system in an abstract, symbolic way. The fundamental idea is to lump all the states in a region into a single abstract element and to then represent the entire system with a finite number of these elements. Control laws

Motion Description Languages and Symbolic Control, Fig. 1 Simple example of symbolic control with a focus on abstracting the inputs. Two systems, a snake-like robot and an autonomous car, are given a high-level plan in terms of symbols for navigating a right-hand turn.

The systems each interpret the same symbols in their own ways, leading to different trajectories due both to differences in dynamics but also to different sensors cues as caused, for example, by the parked vehicle encountered by the car in this scenario

are then defined that steer all the states in one element into some state in a different region. The symbolic control system is then the finite set of elements representing regions together with the finite set of controllers for moving between them. It can be thought of essentially as a graph (or more accurately as a transition system) in which the nodes represent regions in the state space and the edges represent achievable transitions between them. The goal of this abstraction step is for the two representations to be equivalent (or at least approximately equivalent) in that any motion that can be achieved in one can be achieved in the other (in an appropriate sense). Planning and analysis can then be done on the (simpler) symbolic model. Further details on such schemes can be found in, for example, Tabuada (2006) and Bicchi et al. (2006).

As an illustrative example, consider as before a snake-like robot moving through a right-hand turn. In a simplified view of this second approach to symbolic control, one begins by dividing the environment up into regions and then defining controllers to steer the robot from region to region as illustrated in the left image in Fig. 2. This yields the symbolic model shown in the center of Fig. 2. A plan is then developed on this model to move from the initial position to the final position. This planning step can take into account restrictions on the motion and subgoals of the task. Here, for example, one may want the robot to stay to the right of the double yellow line, which is in its lane of traffic. The plan $R_2 \rightarrow R_4 \rightarrow R_6 \rightarrow R_8 \rightarrow R_9 \rightarrow R_{10}$ is one sequence that drives the system around the turn while satisfying the lane requirement. Each transition in the sequence corresponds to a control law. The plan is then executed by applying the sequence of control laws, resulting in the actual trajectory shown in the right image in Fig. 2.

Applications and Connections

The fundamental idea behind symbolic control, namely, mitigating complexity by abstracting a system, its environment, and even the tasks to be accomplished into a simpler but (approximately)

equivalent model, is a natural and a powerful one. It has clear connections to both hybrid systems (Brockett 1993; Egerstedt 2002) and to quantized control (Bicchi et al. 2006), and the tools from those fields are often useful in describing and analyzing systems with symbolic representations of the control and of the dynamics. Symbolic control is not, however, strictly a subcategory of either field, and it provides a unique set of tools for the control and analysis of dynamic systems.

Brockett's original MDL was intended to serve as a tool for describing and planning robot motion. Inspired in part by this, languages for motion continue to be developed. Some of these extend and provide a more formal basis for motion programming (Manikonda et al. 1998) and interconnection of dynamic systems into a single whole (Murray et al. 1992), while some are designed for specialized dynamics or applications such as flight vehicles (Frazzoli et al. 2005), self-assembly (Klavins 2007), and other areas. In addition to studying standard systems and control theoretic ideas, including notions of reachability (Bicchi et al. 2002) and stability (Tarraf et al. 2008), the framework of symbolic control introduces interesting questions such as how to understand the reduction of complexity that can be achieved for a given collection of symbols (Egerstedt and Brockett 2003).

While there are many application areas of symbolic control, a particularly active one is that of motion planning for autonomous mobile robots (Belta et al. 2007). As illustrated in Figs. 1 and 2, symbolic control allows the planning problem (i.e., the determination of how to achieve a desired task) to be separated from the complexities of the dynamics. The approach has been particularly fertile when coupled with symbolic descriptions of the tasks to be achieved. While point-to-point commands are useful, and can be often thought of as symbols themselves from which to build more complicated commands, most tasks that one would want mobile robots to carry out involve combinations of spatial goals (move to a certain location), sequencing (first do this and then do that), or other temporal requirements (repeatedly visit a collection of regions), as

Motion Description Languages and Symbolic Control, Fig. 2 Simple example of symbolic control with a focus on abstracting the system dynamics and environment. The initial environment (left image) is segmented into different regions and simple controllers developed for moving from region to region. The image shows two possible controllers, one that actuates the robot through a tight slither pattern to move forward by one region and

one that twists the robot to face the cell to the left before slithering across and then reorienting. The combination of regions and actions yields a symbolic abstraction (center image) that allows for planning to achieve specific goals, such as moving through the right-hand turn. Executing this plan leads to a physical trajectory of the system (right image)

well as safety or other restrictions (avoid obstacles or regions that are dangerous for the robot to traverse). Such tasks can be described using a variety of temporal logics. These are, essentially, logic systems that include rules related to time in addition to the standard Boolean operators. These tasks can be combined with a symbolic description of a system, and then automated tools used both to check whether the system is able to perform the desired task as well as to design plans that ensure the system will do so (Fainekos et al. 2009). This symbolic approach to the design of control systems finds application in other domains as well, including systems biology and bioinformatics (Bartocci et al. 2018).

Summary and Future Directions

Symbolic control proceeds from the basic goal of mitigating the complexity of dynamic systems, especially in real-world scenarios, to yield a simplification of the problems of analysis and control design. It builds upon results from diverse fields while also contributing new ideas to those areas, including hybrid system theory, formal languages

and grammars, and motion planning. There are many open, interesting questions that are the subject of ongoing investigations as well as the genesis of future research.

One particularly fruitful direction is that of combining symbolic control with stochasticity. Systems that operate in the real world are subject to noise both with respect to their inputs (noisy actuators) and to their outputs (noisy sensors). Recent work along these lines can be found in the formal method approach to motion planning and in hybrid systems (Lahijanian et al. 2012; Abate et al. 2011). The fundamental idea is to use a Markov chain, Markov decision process, or similar model as the symbolic abstraction and then, as in all symbolic control, to do the analysis and planning on this simpler model.

Another interesting direction is to address questions of optimality with respect to the symbols and abstractions for a given dynamic system. Of course, the notion of “optimal” must be made clear, and there are several reasonable notions one could define. There is a clear trade-off between the complexity of individual symbols, the number of symbols used in the motion “alphabet,” and the complexity in terms of, say, average number of symbols required to code programs that achieve a

given set of tasks. The complexity of a necessary alphabet is also related to the variety of tasks the system might need to perform. An autonomous vacuuming robot is likely to need far fewer symbols in its library than an autonomous vehicle that must operate in everyday traffic conditions and respond to unusual events such as traffic jams. The question of the “right” set of symbols can also be of use in efficient descriptions of motion in domains such as dance (Baillieul and Ozcimder 2014).

It is intuitively clear that to handle complex scenarios and environments, a hierarchical approach is likely needed. Organizing symbols into progressively higher levels of abstraction should allow for more efficient reasoning, planning, and reaction to real-world settings. Such structures already appear in existing works, such as in the behavior-based approach of Brooks (1986), in the extended motion description language in Manikonda et al. (1998), and in the Spatial Semantic Hierarchy of Kuipers (2000). Despite these efforts, there is still a need for a rigorous approach for analyzing and designing symbolic hierarchical systems.

The final direction discussed here is that of the connection of symbolic control to emergent behavior in large groups of dynamic agents. There are a variety of intriguing examples in nature in which large numbers of agents following simple rules produce large-scale, coherent behavior, including in fish schools and termite and ant colonies (Johnson 2002). How can one predict the global behavior that will emerge from a large collection of independent agents following simple rules (symbols)? How can one design a set of symbols to produce a desired collective behavior? While there has been some work in symbolic control for self-assembling systems (Klavins 2007), this general topic remains a rich area for research.

Motion Planning for Marine Control Systems

Andrea Caiti

DII – Department of Information Engineering and Centro “E. Piaggio”, ISME – Interuniversity Research Centre on Integrated Systems for the Marine Environment, University of Pisa, Pisa, Italy

Abstract

In this chapter we review motion planning algorithms for ships, rigs, and autonomous marine vehicles. Motion planning includes path and trajectory generation, and it goes from optimized route planning (off-line long-range path generation through

operating research methods) to reactive on-line trajectory reference generation, as given by the guidance system. Crucial to the marine systems case is the presence of environmental external forces (sea state, currents, winds) that drive the optimized motion generation process.

Keywords

Configuration space · Dynamic programming · Grid search · Guidance controller · Guidance system · Maneuvering · Motion plan · Optimization algorithms · Path generation · Route planning · Trajectory generation · World space

Introduction

Marine control systems include primarily ships and rigs moving on the sea surface, but also underwater systems, manned (submarines) or unmanned, and eventually can be extended to any kind of off-shore moving platform.

A *motion plan* consists in determining what motions are appropriate for the marine system to reach a goal, or a target/final state (LaValle 2006). Most often, the final state corresponds to a geographical location or destination, to be reached by the system while respecting constraints of physical and/or economical nature. Motion planning in marine systems hence starts from *route planning*, and then it covers desired *path generation* and *trajectory generation*. Path generation involves the determination of an ordered sequence of states that the system has to follow; trajectory generation requires that the states in a path are reached at a prescribed time.

Route, path, and trajectory can be generated off-line or on-line, exploiting the feedback from the system navigation and/or from external sources (weather forecast, etc.). In the feedback case, planning overlaps with the *guidance system*, i.e., the continuous computation of the reference (desired) state to be used as reference input by the motion control system (Fossen 2011).

Formal Definitions and Settings

Definitions and classifications as in Goerzen et al. (2010) and Petres et al. (2007) are followed throughout the section. The marine systems under considerations live in a physical space referred to as the *world space* (e.g., a submarine lives in a 3-D Euclidean space). A *configuration* q is a vector of variables that define position and orientation of the system in the world space. The set of all possible configurations is the *configuration space*, or *C-space*. The vector of configuration and configuration rate of changes is the *state* of the system $\mathbf{x} = [q^T \dot{q}^T]^T$, and the set of all the possible states is the *state space*. The kino-dynamic model associated to the system is represented by the system *state equations*. The regions of *C-space* free from obstacles are called *C-free*.

The *path planning* problem consists in determining a curve $\gamma: [0, 1] \rightarrow C\text{-free}, s \rightarrow \gamma(s)$, with $\gamma(0)$ corresponding to the initial configuration and $\gamma(1)$ corresponding to the goal configuration. Both initial and goal configurations are in *C-free*. The *trajectory planning* problem consists in determining a curve γ and a *time law*: $t \rightarrow s(t)$ s.t. $\gamma(s) = \gamma(s(t))$. In both cases, either the path or the trajectory must be compatible with the system state equations. In the following, definitions of motion algorithm properties are given referring to path planning, but the same definitions can be easily extended to trajectory planning.

A motion planning algorithm is *complete* if it finds a path when one exists, and returns a proper flag when no path exists. The algorithm is *optimal* when it provides the path that minimizes some cost function J . The (strictly positive) cost function J is *isotropic*, when it depends only on the system configuration ($J = J(q)$), or *anisotropic*, when it depends also on an external force field $\mathbf{f}$ (e.g., sea currents, sea state, weather perturbations) ($J = J(q, \mathbf{f})$). The cost function J induces a *pseudometric* in the configuration space; the distance d between configurations q_1 and q_2 through the path γ is the “cost-to-go” from q_1 to q_2 along γ :

$$d(q_1, q_2) = \int_0^1 J(\gamma_{q_1 q_2}(s), \mathbf{f}) ds \quad (1)$$

An optimal motion planning problem is:

- *Static* if there is perfect knowledge of the environment at any time, *dynamic* otherwise
- *Time-invariant* when the environment does not evolve (e.g., coastline that limits the *C-free* subspace), *time-variant* otherwise (e.g., other systems – ships, rigs – in navigation)
- *Differentially constrained* if the system state equations act as a constraint on the path, *differentially unconstrained* otherwise

In practice, optimal motion planning problems are solved numerically through discretization of the *C-space*. *Resolution* completeness/optimality of an algorithm implies the achievement of the solution as the discretization interval tends to zero. *Probabilistic* completeness/optimality implies that the probability of finding the solution tends to 1 as the computation time approaches infinity. *Complexity* of the algorithm refers to the computational time required to find a solution as a function of the dimension of the problem.

The scale of the motion w.r. to the scale of the system defines the specific setting of the problem. In cargo ships route planning from one port call to the next, the problem is stated first as static, time-invariant, differentially unconstrained *path* planning problem; once a large-scale route is thus determined, it can be refined on smaller scales, e.g., smoothing it, to make it compatible with ship maneuverability. Maneuvering the same cargo ship in the approaches to a harbor has to be casted as a dynamic, time-variant, differentially constrained *trajectory* planning problem.

Large-Scale, Long-Range Path Planning

Route determination is a typical long-range path planning problem for a marine system. The geographical map is discretized into a grid, and the optimal path between the approaches of the

starting and destination ports is determined as a sequence of adjacent grid nodes. The problem is taken as time-invariant and differentially unconstrained, at least in the first stages of the procedure. It is assumed that the ship will cruise at its own (constant) most economical speed to optimize bunker consumption, the major source of operating costs (Wang and Meng 2012). Navigation constraints (e.g., allowed ship traffic corridors for the given ship class) are considered, as well as weather forecasts and predicted/prevaling currents and winds. The cost-to-go Eq. (1) is built between adjacent nodes either in terms of time to travel or in terms of operating costs, both computed correcting the nominal speed with the environmental forces. Optimality is defined in terms of shortest time/minimum operating cost; the anisotropy introduced by sea/weather conditions is the driving element of the optimization, making the difference with respect to straightforward shortest route computation. The approach is iterated, starting with a coarse grid and then increasing grid resolution in the neighborhood of the previously found path.

The most widely used optimization approach for surface ships is *dynamic programming* (LaValle 2006); alternatively, since the determination of the optimal path along the grid nodes is equivalent to a search over a graph, the *A** algorithm is applied (Delling et al. 2009). As the discretization grid gets finer, system dynamics are introduced, accounting for ship maneuverability and allowing for deviation from the constant ship speed assumption. Dynamic programming allows to include system dynamics at any level of resolution desired; however, when system dynamics are considered, the problem dimension grows from 2-D to 3-D (2-D space plus time).

In the case of underwater navigation, path planning takes place in a 3-D world space, and the inclusion of system dynamics makes it a 4-D problem; moreover, bathymetry has to be included as an additional constraint to shape the *C-free* subspace. Dynamic programming may become unfeasible, due to the increase in dimensionality. Computationally feasible

algorithms for this case include global search strategies with probabilistic optimality, as *genetic algorithms* (Alvarez et al. 2004), or improved grid-search methods with resolution optimality, as FM* (Petres et al. 2007).

Environmental force fields are intrinsically dynamic fields; moreover, the prediction of such fields at the moment of route planning may be updated as the ship is in transit along the route. The path planning algorithms can/must be rerun, over a grid in the neighborhood of the nominal path, each time new environmental information becomes available. Kino-dynamic model of the ship must be included, allowing for deviation from the established path and ship speed variation around the nominal most economical speed. The latter case is particularly important: increasing/decreasing the speed to avoid a weather perturbation keeping the same route may indeed result in a reduced operating cost with respect to path modifications keeping a constant speed. This implies that the timing over the path must be specified. Dynamic programming is well suited for this transition from path to trajectory generation, and it is still the most commonly used approach to trajectory (re)planning in reaction to environmental predictions update.

When discretizing the world space, the minimum grid size should still be large enough to allow for ship maneuvering between grid nodes. This is required for safety, to allow evasive maneuvering when other ships are at close ranges, and for the generation of smooth, dynamics-compliant trajectories between grid points. This latter aspect bridges motion planning with guidance.

Trajectory Planning, Maneuvering Generation, and Guidance Systems

Once a path has been established over a spatial grid, a continuous reference has to be generated, linking the nodes over the grid. The generation of the reference trajectory has to take into account all the relevant dynamic properties and constraints of the marine system, so that the

Motion Planning for Marine Control Systems, Fig. 1 Generation of a reference trajectory with a system model and a guidance controller (Adapted from Fossen (2011))

reference motion is *feasible*. In this scenario, the path/trajectory nodes are *way-points*, and the trajectory generation connects the way-points along the route. The approaches to trajectory generation can be divided between those that do not compute explicitly in advance the whole trajectory and those that do.

Among the approaches that do not need explicit trajectory computation between way-points, the most common is the *line-of-sight* (LOS) guidance law (Pettersen and Lefeber 2001). LOS guidance can be considered a path generation, more than a trajectory generation, since it does not impose a time law over the path; it computes directly the desired ship reference heading on the basis of the current ship position and the previous and next way-point positions. A review of other guidance approaches can be found in Breivik and Fossen (2008), where maneuvering along the path and steering around the way-points are also discussed. From such a set of different maneuvers, a library of motion primitives can be built (Greytak and Hover 2010), so that any motion can be specified as a sequence of primitives. While each primitive is feasible by construction, an arbitrary sequence of primitives may not be feasible. An optimized search algorithm (dynamic programming, A*) is again needed to determine the optimal feasible maneuvering sequence.

Path/trajectory planning explicitly computing the desired motion among two way-points may include a system dynamic model, or may not. In the latter case, a sufficiently smooth curve that connects two way-points is generated, for

instance, as splines or as Dubins paths (LaValle 2006). Curve generation parameters must be set so that the “sufficiently smooth” part is guaranteed. After curve generation, a trim velocity is imposed over the path (path planning), or a time law is imposed, e.g., smoothly varying the system reference velocity with the local curvature radius.

Planners that do use a system dynamic model are described in Fossen (2011) as part of the guidance system. In practice, the dynamic model is used in simulation, with a (simulated) feedback controller (*guidance controller*), the next way-point as input, and the (simulated) system position and velocity as output. The simulated results are feasible maneuvers by construction and can be given as reference position/velocity to the physical control system (Fig. 1).

Summary and Future Directions

Motion planning for marine control systems employs methodological tools that range from operating research to guidance, navigation, and control systems. A crucial role in marine applications is played by the anisotropy induced by the dynamically changing environmental conditions (weather, sea state, winds, currents – the external force fields). The quality of the plan will depend on the quality of environmental information and predictions.

While motion planning can be considered a mature issue for ships, rigs, and even standalone autonomous vehicles, current and future research

directions will likely focus on the following items:

- Coordinated motion planning and obstacle avoidance for *teams* of autonomous surface and underwater vehicles (Aguiar and Pascoal 2012; Casalino et al. 2009)
- Naval traffic regulation compliant maneuvering in restricted spaces and collision evasion maneuvering (Tam and Bucknall 2010)
- Underwater intervention robotics (Antonelli 2006; Sanz et al. 2010)

Motion Planning for PDEs

Thomas Meurer

Automatic Control Chair, Faculty of
Engineering, Kiel University, Kiel, Germany

Abstract

Motion planning or trajectory planning, respectively, refers to the design of an open-loop control to achieve desired trajectories for the system states or outputs. Given distributed parameter systems that are governed by partial differential equations (PDEs), this requires to take into account the spatial-temporal system dynamics. In this case flatness-based techniques provide a systematic motion planning approach, which is based on the parametrization of any system variable by means of a flat or basic output. With this, the motion planning problem can be solved rather intuitively as is illustrated subsequently for linear and semi-linear PDEs. In addition constraints on system input or states can be taken into account systematically by introducing a dynamic optimization problem for the computation of the flat output trajectory.

Keywords

Motion planning · Trajectory planning · Flatness · Formal integration · Trajectory assignment · Transition path · Gevrey class · Dynamic optimization · Spectral decomposition · Riesz spectral operators

Introduction

Motion planning or trajectory planning refers to the design of an open-loop control to realize prescribed desired temporal or spatial-temporal paths for the system states or outputs. Examples include smart structures with embedded actuators and sensors such as adaptive optics in telescopes; adaptive wings or smart

skins; thermal and reheating processes in steel industry and deep drawing; start-up, shutdown, or transitions between operating points in chemical engineering; as well as multi-agent deployment and formation control (see, e.g., the overview in Meurer 2013 or the applications in Schröck et al. 2013; Böhm and Meurer 2017; Kater and Meurer 2019).

For the solution of the motion planning and tracking control problem for finite-dimensional linear and nonlinear systems, differential flatness as introduced in Fliess et al. (1995) has evolved into a well-established inversion-based technique. Differential flatness implies that any system variable can be parametrized in terms of a flat output and its time derivatives up to a problem-dependent order. This yields the favorable property that the assignment of a suitable desired trajectory for the flat output directly provides the open-loop input trajectory required to realize the corresponding state trajectory and thus the prescribed motion. Moreover finite-dimensional nonlinear systems are exactly feedback linearizable by means of quasi-static feedback control (Fliess et al. 1999; Delaleau and Rudolph 1998).

The idea of parametrizing states and inputs can be adapted to systems governed by partial differential equations (PDEs). For this, different techniques have been developed utilizing operational calculus or spectral theory for linear PDEs, (formal) power series for PDEs involving polynomial nonlinearities, and formal integration for rather general semi-linear PDEs using a generalized Cauchy-Kowalevski approach. Recent extensions, e.g., address flatness-based constrained optimal control or model predictive of boundary controlled PDEs. To illustrate the principle ideas and the evolving research results starting with Fliess et al. (1997), in the following selected techniques are highlighted and are introduced based on example problems. The main part of the exposition is restricted to parabolic PDEs, but the application to motion planning for hyperbolic PDEs is briefly introduced before concluding with possible future research directions.

Linear PDEs

In the following, a scalar linear diffusion-reaction equation is considered in the state variable $x(z, t)$ with in-domain control $v(t)$ and boundary control $u(t)$ governed by

$$\partial_t x(z, t) = \partial_z^2 x(z, t) + rx(z, t) + b(z)v(t) \quad (1a)$$

$$\partial_z x(0, t) = 0, \quad x(1, t) = u(t) \quad (1b)$$

$$x(z, 0) = 0. \quad (1c)$$

This PDE describes a wide variety of thermal and fluid systems including heat conduction and tubular reactors. Herein, $r \in \mathbb{R}$ refer to the reaction coefficient, $b(z)$ denotes the in-domain input characteristics, and the initial state is without loss of generality assumed zero. To solve the motion planning problem for (1), a flatness-based feedforward control is determined to realize a finite-time transition between the initial state and a final stationary state $x_T^*(z)$ to be imposed for $t \geq T$. To illustrate two different approaches, it is subsequently distinguished between boundary and in-domain control.

Formal Integration

Given (1) with $v(t) \equiv 0$, i.e., the boundary controlled linear PDE, the application of formal integration as presented in Schörkhuber et al. (2013) is considered. By solving (1) for $\partial_z^2 x(z, t)$ and formally integrating twice with respect to z , the *implicit* expression

$$x(z, t) = x(0, t) + \int_0^z \int_0^p [\partial_t x(q, t) - rx(q, t)] dq dp \quad (2a)$$

$$u(t) = x(1, t), \quad (2b)$$

is obtained when taking into account the boundary conditions (1b). Expression (2) is the starting point to develop to a flatness-based design systematics for motion planning given boundary controlled PDEs. For this, introduce

$$y(t) = x(0, t), \quad (3)$$

and rewrite (2a) in terms of the sequence of functions $(x^{(n)}(z, t))_{n=0}^\infty$ according to

$$x^{(0)}(z, t) = y(t) \quad (4a)$$

$$x^{(n+1)}(z, t) = x^{(0)}(z, t) + \int_0^z \int_0^p [\partial_t x^{(n)}(q, t) - rx^{(n)}(q, t)] dq dp. \quad (4b)$$

This *explicit* iterative formulation enables us to deduced that $y(t)$ denotes a flat output differentially parametrizing the state variable $x(z, t) = \lim_{n \rightarrow \infty} x^{(n)}(z, t)$ and the boundary input $u(t) = x(1, t)$ provided that the limit exists as $n \rightarrow \infty$. It is worth noting that the iteration admits a solution in the form

$$\begin{aligned} x(z, t) &= \sum_{n=0}^{\infty} \frac{(\partial_t - r)^n}{(2n)!} \circ y(t) \\ &= \sum_{n=0}^{\infty} \frac{1}{(2n)!} \sum_{j=0}^n \binom{n}{j} (-r)^{n-j} \partial_t^j y(t). \end{aligned} \quad (5)$$

The respective boundary input $u(t)$ follows immediately from (2b). In particular, by prescribing a suitable trajectory $t \mapsto y^*(t) \in C^\infty(\mathbb{R})$ for $y(t)$, the evaluation of (4) or (5), respectively, yields the spatial-temporal path $x^*(z, t)$ that is realized by the application of the feedforward control $u^*(t) = x^*(1, t)$. This relies on the uniform convergence of (4) or (5), respectively, with at least a unit radius of convergence in z . For this, the notion of a Gevrey class function is needed (Rodino 1993).

Definition 1 (Gevrey class) The function $y(t)$ is in $G_{D,\alpha}(\Lambda)$, the Gevrey class of order α in $\Lambda \subseteq \mathbb{R}$, if $y(t) \in C^\infty(\Lambda)$, and for every closed subset Λ' of Λ , there exists a $D > 0$ such that $\sup_{t \in \Lambda'} |\partial_t^n y(t)| \leq D^{n+1} (n!)^\alpha$.

The set $G_{D,\alpha}(\Lambda)$ forms a linear vector space and a ring with respect to the arithmetic product of functions which is closed under the standard rules of differentiation. Gevrey class functions of order $\alpha < 1$ are entire and are analytic if $\alpha = 1$.

Theorem 1 *Let $y(t) \in G_{D,\alpha}(\mathbb{R})$ for $\alpha < 2$, then the sequence $(x^{(n)}(z, t))_{n=0}^{\infty}$ with coefficients (4) converges uniformly for any $z \geq 0$.*

The proof of this result is a special case of the general treatise in Schörkhuber et al. (2013) and relies on the analysis of the iteration (4) taking into account the assumptions on the function $y(t)$.

Spectral Approach

For (1) with $u(t) \equiv 0$, i.e., in-domain control only, the spectral design approach presented in Meurer (2011, 2013) is illustrated. It should be pointed out that this approach is applicable also to the boundary controlled or the mixed boundary and in-domain controlled PDE and linear PDEs with higher-dimensional spatial domain. By introducing the state space $X = L^2([0, 1])$ and the state variable $x(t) = x(\cdot, t) \in X$, system (1) with $u(t) \equiv 0$ can be rewritten in abstract form as

$$\partial_t x(t) = \mathfrak{A}x(t) + \mathfrak{B}v(t), \quad t > 0 \quad (6a)$$

$$\begin{aligned} x(0) &= x_0 \in \mathcal{D}(\mathfrak{A}) \\ &= \{x \in X \mid \partial_z^2 x \in X, \partial_z x(0) = x(1) = 0\}. \end{aligned} \quad (6b)$$

Herein, $\mathfrak{A}x = \partial_z^2 x + rx$ is the system operator with domain $\mathcal{D}(\mathfrak{A})$, and $\mathfrak{B} = b(z)$ is the input operator. In particular, $\mathfrak{A}$ denotes a so-called Riesz spectral operator, whose eigenfunctions $\phi(z) \in \mathcal{D}(\mathfrak{A})$ and adjoint eigenfunctions $\psi(z) \in \mathcal{D}(\mathfrak{A})$ form an orthonormal Riesz basis for X . Moreover, $\mathfrak{A}$ generates a C_0 -semigroup, whose Laplace transform, i.e., the resolvent operator $R(s, \mathfrak{A}) = (s\mathfrak{I} - \mathfrak{A})^{-1} = \sum_{k \in \mathbb{N}} (s - \lambda_k)^{-1} \langle \cdot, \psi_k(z) \rangle \phi_k(z)$ with identity operator $\mathfrak{I}$ and $L^2([0, 1])$ inner product $\langle \cdot, \cdot \rangle$, exists for $s > \sup_{k \in \mathbb{N}} \Re\{\lambda_k\}$ with $\{\lambda_k\}_{k \in \mathbb{N}}$ the eigenvalues of $\mathfrak{A}$. Applying the Laplace transform to (6) provides

$$\begin{aligned} X(s) &= R(s, \mathfrak{A})\mathfrak{B}V(s) \\ &= \sum_{k \in \mathbb{N}} \frac{1}{s - \lambda_k} \langle \mathfrak{B}V(s), \psi_k(z) \rangle \phi_k(z) \end{aligned} \quad (7)$$

For the considered case, the eigenproblem reads $\mathfrak{A}\phi(z) = \lambda\phi(z)$, $\phi(z) \in \mathcal{D}(\mathfrak{A})$ and yields the solution $\lambda_k = r - \mu_k^2$, $\phi_k(z) = \sqrt{2} \cos(\mu_k z)$ for $\mu_k = (2k - 1)\pi/2$ and $\psi_k(z) = \phi_k(z)$ since $\mathfrak{A}$ is self-adjoint.

The formulation (7) admits the determination of a flatness-based state and input parametrization by introducing a flat output. For this, (7) is rewritten according to

$$\begin{aligned} X(s) &= - \sum_{k \in \mathbb{N}} \frac{1}{\lambda_k} \frac{1}{1 - \frac{s}{\lambda_k}} \langle \mathfrak{B}, \psi_k(z) \rangle \phi_k(z) V(s) \\ &= - \sum_{k \in \mathbb{N}} \frac{1}{\lambda_k} \frac{\prod_{j \in \mathbb{N}, j \neq k} (1 - \frac{s}{\lambda_j})}{\prod_{j \in \mathbb{N}} (1 - \frac{s}{\lambda_j})} \langle \mathfrak{B}, \psi_k(z) \rangle \phi_k(z) V(s). \end{aligned} \quad (8)$$

Formally introducing the variable $Y(s)$ by

$$\begin{aligned} V(s) &= \mathcal{D}_v(s)Y(s) \Rightarrow X(s) \\ &= - \sum_{k \in \mathbb{N}} \frac{1}{\lambda_k} \langle \mathfrak{B}, \psi_k(z) \rangle \phi_k(z) \mathcal{D}_k^x(s) Y(s) \end{aligned} \quad (9)$$

with $\mathcal{D}^v(s) = \prod_{j \in \mathbb{N}} (1 - \frac{s}{\lambda_j})$ and $\mathcal{D}_k^x(s) = \prod_{j \in \mathbb{N}, j \neq k} (1 - \frac{s}{\lambda_j})$ shows that $Y(s)$ is a flat output parametrizing state and input in the operational domain. Herein, $\mathcal{D}^v(s)$ and $\mathcal{D}_k^x(s)$ can

be interpreted as (Hadamard) factorizations of entire functions in the complex domain $s \in \mathbb{C}$ (Boas 1954). The time-domain representation follows immediately by taking into account that s corresponds to time differentiation and the fact that an entire function admits a MacLaurin series expansion (Expressions are for the sake of simplicity in the following only written for the input parametrization. The state parametrization follows accordingly.) $\mathcal{D}_v(s) = \sum_{j \in \mathbb{N}} c_j s^{j-1}$ so that

$$v(t) = \mathcal{D}_v(\partial_t) \circ y(t) = \sum_{j \in \mathbb{N}} c_j \partial_t^{j-1} y(t). \quad (10a)$$

These results rely on the uniform convergence of (10), which can be guaranteed under certain conditions for $\mathcal{D}_v(s)$ and the Gevrey regularity of $y(t)$.

Theorem 2 *Let $(\lambda_k)_{k \in \mathbb{N}}$ be the sequence of disjoint eigenvalues of the Riesz spectral operator $\mathfrak{A}$, and let this sequence be of convergence exponent γ . Then $\mathcal{D}_v(s)$ is an entire function of order $\varrho = \gamma$. If in addition $\mathcal{D}_v(s)$ is of finite type, then (10) converges uniformly for $y(t) \in G_{D,\alpha}(\mathbb{R})$ with $\alpha < 1/\varrho$.*

For the proof of this result and the required notions from complex analysis, the reader is referred to Meurer (2013, Theorem 2.4). Given (1) or (6), respectively, with the eigenvalues discussed before, the convergence exponent of $(\lambda_k)_{k \in \mathbb{N}} = (r - ((2k-1)\pi/2)^2)_{k \in \mathbb{N}}$ is $\gamma = 1/2$, and $\mathcal{D}_v(s) = \cos(\sqrt{r-s})/\cos(\sqrt{r})$ is an entire function of order $\varrho = 1/2$ and finite type so that convergence is ensured for Gevrey class functions $y(t)$ of order $\alpha < 2$. The favorable property of this design approach is – besides its applicability to rather general linear PDE problems involving coupled systems and higher-dimensional spatial domains – the possibility to directly include numerical approximation techniques for the determination for the eigenvalue distribution to obtain a very efficient flatness-based design methodology.

Trajectory Assignment

To apply these results for the solution of the motion planning problem to achieve finite-time transitions between stationary profiles, it is crucial to properly assign the desired trajectory $y^*(t)$ for the basic output $y(t)$. For this, observe that stationary profiles $x^s(z) = x^s(z; y^s)$ are due to the flatness property (Classically stationary solutions are to be defined in terms of stationary input values $x^s(1) = u^s$.) for the boundary controlled setup with $v(t) \equiv 0$ governed by

$$0 = \partial_z^2 x^s(z) + r x^s(z) \quad (11a)$$

$$\partial_z x^s(0) = 0, \quad x^s(0) = y^s. \quad (11b)$$

Given the in-domain control for $u(t) \equiv 0$, stationary profiles are with $v^s = y^s$ (apply the final value theorem to (9) or directly consider (10)) obtained by solving

$$0 = \partial_z^2 x^s(z) + r x^s(z) + b(z) y^s \quad (12a)$$

$$\partial_z x^s(0) = 0, \quad x^s(0) = 0. \quad (12b)$$

For both scenarios the assignment of different y^s results in different stationary profiles $x^s(z; y^s)$. The connection between an initial stationary profile $x_0^s(z; y_0^s)$ and a final stationary profile $x_T^s(z; y_T^s)$ is achieved by assigning $y^*(t)$ such that

$$\begin{aligned} y^*(0) &= y_0^s, & y^*(T) &= y_T^s \\ \partial_t^n y^*(0) &= 0, & \partial_t^n y^*(T) &= 0, \quad n \geq 1. \end{aligned}$$

This implies that $y^*(t)$ has to be locally nonanalytic at $t \in \{0, T\}$ and in view of the previous discussion a Gevrey class function of order $\alpha \in (1, 2)$. For specific problems different functions have been suggested fulfilling these properties. In the following, the ansatz

$$y^*(t) = y_0^s + (y_T^s - y_0^s) \Phi_{T,\gamma}(t) \quad (13a)$$

is used with

$$\Phi_{T,\gamma}(t) = \begin{cases} 0, & t \leq 0 \\ \frac{\int_0^t h_{T,\gamma}(\tau) d\tau}{\int_0^T h_{T,\gamma}(\tau) d\tau} & t \in (0, T) \\ 1, & t \geq T \end{cases} \quad (13b)$$

for $h_{T,\gamma}(t) = \exp(-[t/T(1-t/T)]^{-\gamma})$ if $t \in (0, T)$ and $h_{T,\gamma}(t) = 0$ else. It can be shown that (13b) is a Gevrey class function of order $\alpha = 1 + 1/\gamma$ (Fliess et al. 1997). Alternative function are presented, e.g., in Rudolph (2003b).

Simulation Example

In order to illustrate the results of the motion planning procedure described above, let $r = -1$ in (1).

Motion Planning for PDEs, Fig. 1 Simulated spatial-temporal transition path (left) and applied flatness-based feedforward control $u^*(t)$ and desired trajectory $y^*(t)$ (right) for (1) with boundary control

Boundary Control Using Formal Integration

The differential parametrization (4) is evaluated for the desired trajectory $y^*(t)$ defined in (13) for $y_0^s = 0$ and $y_T^s = 1$ with the transition time $T = 1$ and the parameter $\gamma = 2$. With this, the finite-time transition between the zero initial stationary profile $x_0^*(z) = 0$ and the final stationary profile $x_T^*(z) = x_T^s(z) = y_T^s \cosh(z)$ is realized along the trajectory $x(0,t) = y^*(t)$. The corresponding feedforward control and spatial-temporal transition path are shown in Fig. 1.

In-Domain Control Using Spectral Approach

The determined eigenvalues are taken into account to evaluate the differential parametrization (10) for the desired trajectory $y^*(t)$ defined in (13) for $y_0^s = 0$ and $y_T^s = 20$ with the transition time $T = 0.5$ and the parameter $\gamma = 2$. The spatial input characteristics is chosen asymmetrically with $b(z) = \sigma(z - 0.3) - \sigma(z - 0.5)$ and $\sigma(\cdot)$ the Heaviside function. The resulting finite-time transition from the zero initial stationary profile $x_0^*(z) = 0$ to the final stationary profile $x_T^*(z) = x_T^s(z)$ and the computed feedforward control are depicted in Fig. 2.

Extensions and Generalizations

The previous considerations provide a first introduction to systematic approaches for the

solution of the motion planning problem for systems governed by PDEs. The techniques can be further generalized to address coupled systems of PDEs, certain classes of nonlinear PDEs (see also section “Semi-linear PDEs”), joint boundary and in-domain control, or PDEs with higher-dimensional spatial domain (Rudolph 2003a; Meurer 2011, 2013).

Constrained motion planning and optimal control have been recently addressed by introducing a dynamic optimization problem based on an integrator chain for computation of the flat output trajectory (Andrej and Meurer 2018). Herein, the highest derivative serves as decision variable so that in view of the differential state and input parametrization in terms of the flat output or the states of the integrator chain, respectively, the constrained optimal control problem can be completely expressed in terms of the new decision variable. An extension to flatness-based model predictive control for PDEs is available in Meurer and Andrej (2018).

Besides the many theoretical contributions experimental results for flexible beam and plate structures with embedded piezoelectric actuators (Schröck et al. 2013; Kater and Meurer 2019) and for thermal problems in deep drawing (Böhm and Meurer 2017), confirm the applicability of this design approach and the achievable high tracking accuracy when transiently shaping the deflection

Motion Planning for PDEs, Fig. 2 Simulated spatial-temporal transition path (left) and applied flatness-based feedforward control $u^*(t)$ and desired trajectory $y^*(t)$ (right) for (1) with in-domain control

profile or controlling the spatial-temporal temperature distribution during operation.

Semi-linear PDEs

Flatness can be extended to semi-linear PDEs. This is subsequently illustrated for the diffusion-reaction system

$$\partial_t x(z, t) = \partial_z^2 x(z, t) + r(x(z, t)) \quad (14a)$$

$$\partial_z x(0, t) = 0, \quad x(1, t) = u(t) \quad (14b)$$

$$x(z, 0) = 0 \quad (14c)$$

with boundary input $u(t)$. Similar to the previous section, the motion planning problem refers to the determination of a feedforward control $t \mapsto u^*(t)$ to realize finite-time transitions starting at the initial profile $x_0^*(z) = x(z, 0) = 0$ to achieve a final stationary profile $x_T^*(z)$ for $t \geq T$.

Formal Integration

The generalization of the formal integration approach to general semi-linear PDEs is addressed in Schörkhuber et al. (2013) by making use of an abstract Cauchy-Kowalevski theorem in Gevrey classes. Proceeding as for the determination of (2) yields the *implicit* solution

$$x(z, t) = x(0, t)$$

$$+ \int_0^z \int_0^p [\partial_t x(q, t) - r(x(q, t))] dq dp \quad (15a)$$

$$u(t) = x(1, t), \quad (15b)$$

which can be used to develop a flatness-based design systematics for motion planning given semi-linear PDEs. For this, introduce

$$y(t) = x(0, t), \quad (16)$$

and rewrite (15b) in *explicit* form by means of the sequence of functions $(x^{(n)}(z, t))_{n=0}^\infty$ fulfilling

$$x^{(0)}(z, t) = y(t) \quad (17a)$$

$$x^{(n+1)}(z, t) = x^{(n)}(z, t) + \int_0^z \int_0^p [\partial_t x^{(n)}(q, t) - r(x^{(n)}(q, t))] dq dp. \quad (17b)$$

Obviously, $y(t)$ denotes a flat output, which differentially parametrizes $x(z, t) = \lim_{n \rightarrow \infty} x^{(n)}(z, t)$ and $u(t) = x(1, t)$ provided that the limit exists as $n \rightarrow \infty$. As is shown in Schörkhuber et al. (2013), by making use of scales of Banach spaces in Gevrey classes

and abstract Cauchy-Kowalevski theory, the convergence of the parametrized sequence of functions $(x^{(n)}(z, t))_{n=0}^{\infty}$ can be ensured in some compact subset of the domain $z \in [0, 1]$. Besides its general set-up, this approach provides an iteration scheme, which can be directly utilized for a numerically efficient solution of the motion planning problem.

Simulation Example

Let the reaction be subsequently described by

$$r(x(z, t)) = \sin(2\pi x(z, t)). \quad (18)$$

The iterative scheme (17) is evaluated for the desired trajectory $y^*(t)$ defined in (13) for $y_0^s = 0$ and $y_T^s = 1$ with the transition time $T = 1$ and the parameter $\gamma = 1$, i.e., the desired trajectory is of Gevrey order $\alpha = 2$. The resulting feedforward control $u^*(t)$ and the spatial-temporal transition path resulting from the numerical solution of the PDE are depicted in Fig. 3. The desired finite-time transition between the zero initial stationary profile $x_0^*(z) = 0$ and the final stationary profile $x_T^*(z) = x_T^s(z)$ determined by

$$0 = \partial_z^2 x^s(z) + r(x^s(z)) \quad (19a)$$

$$\partial_z x^s(0) = 0, \quad x^s(0) = y^s. \quad (19b)$$

is clearly achieved along the prescribed path $y^*(t)$.

Extensions and Generalizations

Generalizations of the introduced formal integration approach to solve motion planning problems for systems of coupled PDEs are, e.g., provided in Schörkhuber et al. (2013). Moreover, linear diffusion-convection-reaction systems with spatially and time-varying coefficients defined on a higher-dimensional parallelepipedon are addressed, e.g., in Meurer and Kugi (2009) and Meurer (2013). Novel applications to address motion planning for the deployment and formation control of multi-agent continua using linear, semi- and quasi-linear PDEs are, e.g., considered in Meurer and Krstic (2011), Qi et al (2015), and Freudenthaler and Meurer (2016).

Hyperbolic PDEs

Hyperbolic PDEs exhibiting wavelike dynamics require the development of a design systematics explicitly taking into account the finite speed of wave propagation. For linear hyperbolic PDEs, operational calculus has been successfully applied to determine the state and input

Motion Planning for PDEs, Fig. 3 Simulated spatial-temporal transition path (left) and applied flatness-based feedforward control $u^*(t)$ and desired trajectory $y^*(t)$ (right) for (14) with (18)

parametrizations in terms of the flat output and its advanced and delayed arguments (Rouchon 2001; Petit and Rouchon 2001, 2002; Woittennek and Rudolph 2003; Rudolph and Woittennek 2008). In addition, the method of characteristics can be utilized to address both linear as well as quasi-linear hyperbolic PDEs. Herein, a suitable change of coordinates enables to reformulate the PDE in a normal form, which can be (formally) integrated in terms of a basic output. With this, also an efficient numerical procedure can be developed to solve motion planning problems for hyperbolic PDEs (Woittennek and Mounier 2010; Knüppel et al 2010).

Summary and Future Directions

Motion planning constitutes an important design step when solving control problems for systems governed by PDEs. This is particularly due to the increasing demands on quality, accuracy, and efficiency, which require to turn away from the pure stabilization of an operating point towards the realization of specific start-up, transition, or tracking tasks. It is a favorable property of the above introduced techniques that once the parametrization of states and inputs in terms of the flat output is computed, the numerical evaluation can be performed on the fly, which is particularly useful in online evaluations under real-time constraints. In view of these aspects, future research directions might deepen and further evolve

- semi-analytic design techniques taking into account suitable approximation and model order reduction schemes for complex-shaped spatial domains,
- nonlinear PDEs and coupled systems of nonlinear PDEs with boundary and in-domain control, and
- applications arising, e.g., in multi-agent systems, swarm dynamics, aeroelasticity, fluid flow, and fluid-structure interaction.

Motorcycle Dynamics and Control

Martin Corless

School of Aeronautics and Astronautics, Purdue University, West Lafayette, IN, USA

Abstract

A basic model due to Sharp which is useful in the analysis of motorcycle behavior and control is developed. This model is based on linearization of a bicycle model introduced by Whipple, but is augmented with a tire model in which the lateral tire force depends in a dynamic fashion on tire behavior. This model is used to explain some of the important characteristics of motorcycle behavior. The significant dynamic modes exhibited by this model are capsize, weave, and wobble.

Keywords

Motorcycle · Tire model · Single-track vehicle · Bicycle · Weave · Wobble · Capsize · Counter-steering

Introduction

The bicycle is mankind's ultimate solution to the quest for a human-powered vehicle (Herlihy 2006; Limebeer and Sharp 2006). The motorcycle just makes riding more fun. Bicycles, motorcycles, scooters, and mopeds are all examples of single-track vehicles and have similar dynamics. The dynamics of a motorcycle are considerably more complicated than that of a four-wheel vehicle such as a car. The first obvious difference in behavior is stability. An unattended upright stationary motorcycle is basically an inverted pendulum and is unstable about its normal upright position, whereas a car has no stability issues in the same configuration. Another difference is that a motorcycle must lean when cornering. Although a car leans a little due to suspension travel, there is no necessity for it to lean in

cornering. A perfectly rigid car would not lean. Furthermore, beyond low speeds, the steering behavior of a motorcycle is not intuitive like that of a car. To turn a car right, the driver simply turns the steering wheel right; on a motorcycle the rider initially turns the handlebars to the left. This is called counter-steering and is not intuitive.

A Basic Model

To obtain a basic motorcycle model, we start with four rigid bodies: the **rear frame** (which includes a rigidly attached rigid rider), the **front frame** (includes handlebars and front forks), the **rear wheel**, and the **front wheel**; see Fig. 1. We assume that both frames and wheels have a plane of symmetry which is vertical when the bike is in its nominal upright configuration. The front frame can rotate relative to the rear frame about the **steering axis**; the steering axis is in the plane of symmetry of each frame, and, in the nominal upright configuration of the bike, the angle it makes with the vertical is called the **rake angle** or **caster angle** and is denoted by ϵ . The rear wheel rotates relative to the rear frame about an axis perpendicular to the rear plane of symmetry and is symmetrical with respect to this axis. The same relationship holds between the front wheel and the front frame. Although each wheel can be three-dimensional, we model the wheels as terminating in a knife edge at their boundaries and contact the ground at a single point. Points

Motorcycle Dynamics and Control, Fig. 1 Basic model

P and Q are the points on the ground in contact with the rear and front wheels, respectively.

Each of the above four bodies is described by their mass, mass center location, and a 3×3 inertia matrix. Two other important parameters are the **wheelbase** w and the **trail** c . The wheelbase is the distance between the contact points of the two wheels in the nominal configuration, and the trail is the distance from the front wheel contact point Q to the intersection S of the steering axis with the ground. The trail is normally positive, that is, Q is behind S . The point G locates the mass center of the complete bike in its nominal configuration, whereas G_A is the location of the mass center of the **front assembly** (front frame and wheel).

Description of Motion

Considering a right-handed reference frame $e = (\hat{e}_1, \hat{e}_2, \hat{e}_3)$ with origin O fixed in the ground, the bike motion can be described by the location of the rear wheel contact point P relative to O , the orientation of the rear frame relative to e , and the orientation of the front frame relative to the rear frame; see Fig. 2. Assuming the bike is moving along a horizontal plane, the location of P is usually described by Cartesian coordinates x and y . Let reference frame b be fixed in the rear frame

Motorcycle Dynamics and Control, Fig. 2 Description of motion

with $\hat{b}_1$ and $\hat{b}_3$ in the plane of symmetry with $\hat{b}_1$ along the $P - S$ line; see Fig. 2. Using this reference frame, the orientation of the rear frame is described by a 3-1-2 Euler angle sequence which consists of a **yaw** rotation by ψ about the 3-axis followed by a **lean** (roll) rotation by ϕ about the 1-axis and finally by a **pitch** rotation by θ about the 2-axis. The orientation of the front frame relative to the rear frame can be described by the **steer angle** δ . Assuming both wheels remain in contact with the ground, the pitch angle θ is not independent; it is uniquely determined by δ and ϕ . In considering small perturbations from the upright nominal configuration, the variation in pitch is usually ignored. Here we consider it to be zero. Also the dynamic behavior of the bike is independent of the coordinates x , y , and ψ . These coordinates can be obtained by integrating the velocity of P and $\dot{\psi}$.

The Whipple Bicycle Model

The “simplest” model which captures all the salient features of a single-track vehicle for a basic understanding of low-speed dynamics and control is that originally due to Whipple (Whipple 1899). We consider the linearized version of this model which is further expounded on in Meijaard et al. (2007). The salient feature of this model is that there is no **slip** at each wheel. This means that the velocity of the point on the wheel which is instantaneously in contact with the ground is zero; this is point P' in Fig. 3. No slip implies that there is no **sideslip** which means that the velocity of the wheel contact point ($\bar{v}^P$ in Fig. 3) is parallel to the intersection of the wheel plane with the ground plane; the wheel contact point is the point moving along the ground which is in contact with the wheel.

The rest of this article is based on linearization of motorcycle dynamics about an equilibrium configuration corresponding to the bike traveling upright in a straight line at constant forward speed $v := v^P$, the speed of the rear wheel contact point P . In the linearized system, the longitudinal dynamics are independent of the

Motorcycle Dynamics and Control, Fig. 3 No slip: $v^{P'} = 0$

Motorcycle Dynamics and Control, Fig. 4 Some kinematics

lateral dynamics, and, in the absence of driving or braking forces, the speed v is constant.

With no sideslip at both wheels, kinematical considerations (see Fig. 4) show that the yaw rate $\dot{\psi}$ is determined by δ ; specifically for small angles we have the following linearized relationship:

$$\dot{\psi} = v\delta + \mu\dot{\delta} \quad (1)$$

where

$$v = c_\epsilon/w, \quad \mu = cc_\epsilon/w, \quad c_\epsilon = \cos \epsilon. \quad (2)$$

In Fig. 4, δ_f is the effective steer angle, the angle between the intersections of the front wheel plane and the rear frame plane with the ground. It is approximately given by $\delta_f = \delta c_\epsilon$. Thus, we can completely describe the lateral bike dynamics with the roll angle ϕ and the steer angle δ . To obtain the above relationship, first note that, as a consequence of no sideslip, $\bar{v}^P = v\hat{b}_1$ and $\bar{v}^Q$ is perpendicular to $\hat{f}_2$. Taking the dot product of the expression,

$$\bar{v}^Q = \bar{v}^P + (w+c)\dot{\psi}\hat{b}_2 - c(\dot{\psi} + \dot{\delta}_f)\hat{f}_2$$

with $\hat{f}_2$ while noting that $\hat{b}_1 \cdot \hat{f}_2 = -\sin \delta_f$ and $\hat{b}_2 \cdot \hat{f}_2 = \cos \delta_f$ results in

$$0 = -v \sin \delta_f + (w+c)\dot{\psi} \cos \delta_f - c(\dot{\psi} + \dot{\delta}_f).$$

Linearization about $\delta = 0$ yields the desired result.

The relationship in (1) also holds for four-wheel vehicles. There one can achieve a desired constant yaw rate $\dot{\psi}_d$ by simply letting the steer angle $\delta = \dot{\psi}_d/vv$. However, as we shall see, a motorcycle with its steering fixed at a constant steer angle is unstable. Neglecting gyroscopic terms, it is simply an inverted pendulum. With its steering free, a motorcycle can be stable over a certain speed range and, if unstable, can be easily stabilized above a very low speed by most people. Trials riders can stabilize a motorcycle at any speed including zero.

In developing our mathematical model, we initially ignore the mass and inertia of the front assembly along with gyroscopic effects, and we assume that the $\hat{b}_1$ and $\hat{b}_3$ axes are the principal axes of inertia of the bike/rider with moments of inertia I_{xx} and I_{zz} , respectively. Angular momentum considerations yield that

$$\frac{d\tilde{H}^P}{dt} + m\tilde{r}^{PG} \times \tilde{a}^P = \Sigma \tilde{M}^P \quad (3)$$

where $\tilde{H}^P \approx I_{xx}\ddot{\phi}\hat{b}_1 + I_{zz}\ddot{\psi}\hat{b}_3$ is the angular momentum of the rider/bike about point P , $\tilde{a}^P$ is the acceleration of P , $\tilde{r}^{PG} = b\hat{b}_1 - h\hat{b}_3$, and $\Sigma \tilde{M}^P$ is the sum of the external moments on rider/bike about P . Considering the roll component ($\hat{b}_1$ component) of (3) and linearization results in

$$I_{xx}\ddot{\phi} + mha = mgh\phi + (N_f c_\epsilon c)\delta \quad (4)$$

where N_f is the normal force (vertical and upward) on the front wheel and a is the lateral acceleration of point P . Considering the pitch component ($\hat{b}_2$ component) of (3), one can obtain that

$$N_f \approx mgb/w \quad (5)$$

which along with (4) yields

$$I_{xx}\ddot{\phi} - mgh\phi = -mha + \mu mgb\delta. \quad (6)$$

Cornering at Constant Speed

If the speed v and the steer angle δ are constant, then (1) implies that $\dot{\psi}$ is constant and equal to $v\delta$. Since $\dot{\psi}$ and v are constant, point P moves on a circle of radius $R = v/\dot{\psi}$. Using these relationships, one obtains that

$$\delta = 1/vR = w/c_\epsilon R.$$

Since P is moving in a circle of radius R at speed v , $a = v^2/R$. The behavior of (6) is that of an inverted pendulum subject to a constant torque equal to $-mha + \mu mgb\delta$. It is unstable about its equilibrium angle

$$\phi = \frac{a}{g} - \frac{\mu b\delta}{h} = \frac{v^2}{gR} - \frac{bc}{hR}.$$

Hence, except at small speeds, to corner with a lateral acceleration a , the rider/bike must lean into the corner at an angle of approximately a/g radians.

The Lean Equation

Using basic kinematics and recalling relationship (1),

$$a = v\dot{\psi} = v^2\delta + \mu v\dot{\delta}. \quad (7)$$

Equation (6) now yields the lean equation:

$$I_{xx}\ddot{\phi} + c_{\phi\delta}v\dot{\delta} - mgh\phi + (k_{\phi\delta} + k_{\phi\delta_2}v^2)\delta = 0, \quad (8)$$

where

$$\begin{aligned} c_{\phi\delta} &= \mu mh, & k_{\phi\delta} &= -S_A g, \\ k_{\phi\delta_2} &= vmh, & S_A &= \mu mb. \end{aligned}$$

Note that v is a constant parameter corresponding to the nominal speed of the rear wheel contact point.

With $\delta = 0$, we have a system whose behavior is characterized by two real eigenvalues: $\pm\sqrt{mgh/I_{xx}}$. This system is unstable due to the positive eigenvalue $\sqrt{mgh/I_{xx}}$. For v sufficiently large, the coefficient of δ in (8) is positive and one can readily show that the above system can be stabilized with positive feedback $\delta = K\phi$ provided $K > mgh/(k_{\phi\delta} + k_{\phi\delta_2}v^2)$. This helps

explain the stabilizing effect of a rider turning the handlebars in the direction the bike is falling. Actually, the rider input is a **steer torque** T_δ about the steer axis.

Taking into account the mass and inertia of the front assembly, gyroscopic effects, and crossproducts of inertia of the rear frame, one can show (see Meijaard et al. 2007) that the lean equation (8) still holds with the addition of a $m_{\phi\delta}\ddot{\delta}$ term, that is,

$$\boxed{I_{xx}\ddot{\phi} + m_{\phi\delta}\ddot{\delta} + c_{\phi\delta}v\dot{\delta} - mgh\phi + (k_{\phi\delta} + k_{\phi\delta_2}v^2)\delta = 0} \quad (9)$$

where

$$\begin{aligned} m_{\phi\delta} &= \mu I_{xz} + I_{A\epsilon x}, \\ c_{\phi\delta} &= \mu mh + v I_{xz} + \mu S_T + c_\epsilon S_F, \\ k_{\phi\delta} &= -S_A g, \\ k_{\phi\delta_2} &= v(mh + S_T), \\ S_A &= \mu mb + m_A u_A. \end{aligned}$$

Here I_{xx} is the moment of inertia of the total motorcycle and rider in the nominal configuration about the $\hat{b}_1$ axis and I_{xz} is the inertia crossproduct w.r.t the $\hat{b}_1$ and $\hat{b}_3$ axes. The term $I_{A\epsilon x}$ is the front assembly inertia crossproduct with respect to the steering axis and the $\hat{b}_1$ axis; see Meijaard et al. (2007) for a further description of this parameter. m_A is the mass of the front assembly (front wheel and front frame), and u_A is the offset of the mass center of the front assembly from the steering axis, that is, the distance of this mass center from the steering axis; see Fig. 1. The terms $S_F = I_{Fyy}/r_F$ and $S_T = I_{Ryy}/r_R + I_{Fyy}/r_F$ are **gyroscopic** terms due to the rotation of the front and rear wheels where r_F and r_R are the radii of the front and rear wheels, while I_{Fyy} and I_{Ryy} are the moments of inertias of the front and rear wheels about their axles. It is assumed that the mass center of each wheel is located at its geometric center.

The Steer Equation

Considering the yaw component ($\hat{b}_3$ component) of (3), one can obtain that

$$I_{zz}\ddot{\psi} + mba \approx wF^f \quad (10)$$

where F^f is the lateral force on the front wheel. Considering the sum of moments about the steering axis for the front assembly and linearization results in

$$T_\delta + \mu s_\epsilon w N_f \delta + \mu w N_f \phi - \mu w F^f = 0. \quad (11)$$

Combining (11), (10), (5), and (7) yields the steer equation:

$$m_{\delta\delta}\ddot{\delta} + c_{\delta\delta}v\dot{\delta} + k_{\delta\phi}\phi + (k_{\delta\delta} + k_{\delta\delta_2}v^2)\delta = T_\delta \quad (12)$$

where

$$\begin{aligned} m_{\delta\delta} &= \mu^2 I_{zz}, \quad c_{\delta\delta} = \mu (S_A + v I_{zz}), \\ k_{\delta\phi} &= -S_A g, \quad k_{\delta\delta} = -s_\epsilon S_A g, \\ k_{\delta\delta_2} &= v S_A, \quad S_A = \mu mb. \end{aligned}$$

Taking into account the mass and inertia of the front assembly, gyroscopic effects, and crossproducts of inertia of the rear frame, one can show (see Meijaard et al. 2007) that the steer equation (12) still holds with the addition of $m_{\delta\phi}\ddot{\phi}$ and $c_{\delta\phi}v\dot{\phi}$ terms, that is,

$$\boxed{m_{\delta\phi}\ddot{\phi} + m_{\delta\delta}\ddot{\delta} + v c_{\delta\phi}\dot{\phi} + v c_{\delta\delta}\dot{\delta} + k_{\delta\phi}\phi + (k_{\delta\delta} + k_{\delta\delta_2}v^2)\delta = T_\delta} \quad (13)$$

where

$$\begin{aligned} m_{\delta\phi} &= m_{\phi\delta}, \quad m_{\delta\delta} = \mu^2 I_{zz} + 2\mu I_{A\epsilon z} + I_{A\epsilon\epsilon}, \\ c_{\delta\phi} &= -(\mu S_T + c_\lambda S_F), \\ c_{\delta\delta} &= \mu (S_A + v I_{zz}) + v I_{A\epsilon z}, \\ S_A &= \mu mb + m_A u_A, \quad k_{\delta\phi} = k_{\phi\delta}, \\ k_{\delta\delta} &= -s_\epsilon S_A g, \quad k_{\delta\delta_2} = v(S_A + s_\epsilon S_F). \end{aligned}$$

Here, I_{zz} is the moment of inertia of the total motorcycle and rider in the nominal configuration about the $\hat{b}_3$ axis, $I_{A\epsilon\epsilon}$ is the moment of inertia of the front assembly about the steering axis, and $I_{A\epsilon z}$ is the front assembly inertia crossproduct with respect to the steering axis and the vertical axis through P . The lean equation (9) combined with the steer equation (12) provides an initial model for motorcycle dynamics. This is a linear model with the nominal speed v as a constant parameter and the rider's steering torque T_δ as an input.

Modes of the Whipple Model

With $v = 0$, the linearized Whipple model (9), (10), (11), and (12) has two pairs of real eigenvalues: $\pm p_1, \pm p_2$ with $p_2 > p_1 > 0$; see Fig. 5. The pair $\pm p_1$ roughly describes the inverted pendulum behavior of the whole bike with fixed steering. As v increases the real eigenvalues corresponding to p_1 and p_2 meet and from there on form a complex conjugate pair of eigenvalues which result in a single oscillatory mode called the **weave mode**. Initially the weave mode is unstable, but is stable above a certain speed v_w , and for large speeds, its eigenvalues are roughly a linear function of v ; thus, it becomes more damped and its frequency increases with speed. The eigenvalue corresponding to $-p_2$ remains real and becomes more negative with speed; this is called the **castor mode**, because it roughly corresponds to the front assembly castoring about the steer axis. The eigenvalue corresponding to $-p_1$ also remains real but increases, eventually becoming slightly positive above some speed v_c ,

Motorcycle Dynamics and Control, Fig. 5 Variation of eigenvalues of Whipple model with speed v

resulting in an unstable system; the corresponding mode is called the **capsize mode**. Thus, the bike is stable in the autostable speed range (v_w, v_c) and unstable outside this speed range. However, above v_c , the unstable capsize mode is easily stabilized by a rider and usually without conscious effort. This is because the time-constant of the unstable capsize mode is very small (Astrom et al. 2005).

Sharp71 Model (Sharp 1971)

The Whipple bicycle model is not applicable at higher speeds. In particular, it does not contain a **wobble mode** which is common to bicycle and motorcycle behavior at higher speeds. A wobble mode is characterized mainly by oscillation of the front assembly about the steering axis and can sometimes be unstable. Also, in a real motorcycle, the damping and frequency of the weave mode do not continually increase with speed; the damping usually starts to decrease after a certain speed; sometimes this mode even becomes unstable. At higher speeds, one must depart from the simple non-slipping wheel model. In the Whipple model, the lateral force F on a wheel is simply that force which is necessary to maintain the non-holonomic constraint which requires the velocity of the wheel contact point to be parallel to the wheel plane, that is, no sideslip. Actual tires on wheels slip in the longitudinal and lateral direction and the lateral force depends on slip in the lateral direction, that is, sideslip. This lateral slip is defined by the **slip angle** α which is the angle between the contact point velocity and the intersection of the wheel plane and the ground; see Fig. 6.

The lateral force also depends on the tire **camber angle** which is the roll angle of the tire; motorcycle tires can achieve large camber angles in cornering; modern MotoGP racing motorcycles can achieve camber angles of nearly 65° . An initial linear model of a tire lateral force is given by

$$F = N(-k_\alpha \alpha + k_\phi \phi) \quad (14)$$

where N is the normal force on the tire, $k_\alpha > 0$ is called the tire **cornering stiffness**, and $k_\phi > 0$ is

Motorcycle Dynamics and Control, Fig. 6 Lateral force, slip angle, and camber angle

called the **camber stiffness**. Since lateral forces do not instantaneously respond to changes in slip angle and camber, the dynamic model,

$$\frac{\sigma}{v} \dot{F} + F = N(-k_{\alpha}\alpha + k_{\phi}\phi), \quad (15)$$

is usually used where $\sigma > 0$ is called the **relaxation length** of the tire. This yields more realistic behavior (Sharp 1971) and results in the appearance of the wobble mode. In this model the weave mode damping eventually decreases at higher speeds and the frequency does not continually increase. The frequency of the wobble mode is higher than that of the weave mode and its damping decreases at higher speeds.

Further Models

To obtain nonlinear models, resort is usually made to multi-body simulation codes. In recent years, several researchers have used such codes to make nonlinear models which take into account other features such as frame flexibility, rider models, and aerodynamics; see Cossalter (2002), Cossalter and Lot (2002), Sharp and Limebeer (2001), and Sharp et al. (2004). The nonlinear behavior of the tires is usually modeled with a version of the **Magic formula**; see Pacejka (2006), Sharp et al. (2004), and Cossalter et al. (2003). Another line of research is to use some of these models to obtain optimal trajectories for high performance; see Saccon et al. (2012).

Moving Horizon Estimation

James B. Rawlings and Douglas A. Allan
Department of Chemical Engineering, University of California, Santa Barbara, CA, USA

Abstract

Moving horizon estimation (MHE) is a state estimation method that is particularly useful for nonlinear or constrained dynamical systems for which few general methods with established properties are available. This article explains the concept of full information

estimation and introduces moving horizon estimation as a computable approximation of full information. To obtain a tractable approximation, the moving horizon method considers a fixed-sized window of only the most recent measurements, and therefore the horizon window *moves* in time with the data. The basic design methods for ensuring stability of MHE are presented. Relationships of full information and MHE to other state estimation methods such as Kalman filtering and statistical sampling are discussed.

Keywords

State estimation · Kalman filtering · Particle filtering

Introduction

In state estimation, we consider a dynamical system from which measurements are available. In discrete time, the system description is

$$x^+ = f(x, w) \quad y = h(x) + v \quad (1)$$

The state of the systems is $x \in \mathbb{R}^n$, the measurement is $y \in \mathbb{R}^p$, and the notation x^+ means x at the next sample time. A control input u may be included in the model, but it is considered a known variable, and its inclusion is irrelevant to state estimation, so we suppress it in the model under consideration here. We receive measurement y from the sensor, but the process disturbance, $w \in \mathbb{R}^g$; measurement disturbance, $v \in \mathbb{R}^p$; and system initial state, $x(0)$, are considered unknown variables.

The goal of state estimation is to construct or estimate the trajectory of x from only the measurements y . Note that for control purposes, we are usually interested in the estimate of the state at the current time, T , rather than the entire trajectory over the time interval $[0, T]$. In the moving horizon estimation (MHE) method, we use optimization to achieve this goal. We have two sources of error, the state transition is affected by an unknown process disturbance (or noise),

w , and the measurement process is affected by another disturbance, v . In the MHE approach, we formulate the optimization objective to minimize the size of these errors, thus finding a trajectory of the state that comes close to satisfying the (error-free) model while still fitting the measurements.

First, we define some notation necessary to distinguish the system variables from the estimator variables. We have already introduced the system variables (x, w, y, v) . In the estimator optimization problem, these have corresponding decision variables, which we denote by the Greek letters $(\chi, \omega, \eta, \nu)$. The relationships between these variables are

$$\chi^+ = f(\chi, \omega) \quad y = h(\chi) + \nu \quad (2)$$

and they are depicted in Fig. 1. Notice that ν measures the gap between the model prediction $\eta = h(\chi)$ and the measurement y . The *optimal* decision variables are denoted $(\hat{x}, \hat{w}, \hat{y}, \hat{v})$, and these optimal decisions are the estimates provided by the state estimator.

Full Information Estimation

The objective function for full information estimation (FIE) is

$$V_T(\chi(0), \omega) = \ell_x(\chi(0) - \bar{x}_0) + \sum_{i=0}^{T-1} \ell_d(\omega(i), \nu(i)) \quad (3)$$

subject to (2), in which T is the current time, ω is the estimated sequence of process disturbances, $(\omega(0), \dots, \omega(T-1))$, $y(i)$ is the measurement at time i , and $\bar{x}_0$ is the prior, i.e., available, value of the initial state. *Full information* here means that we use *all* the data on time interval $[0, T]$ to estimate the state (or state trajectory) at time T . The stage cost $\ell_d(\omega, \nu)$ costs the model disturbance and the fitting error, the two error sources that we reconcile in all state estimation problems.

The full information estimator is then defined as the solution to

Moving Horizon Estimation, Fig. 1 The state, measured output, and disturbance variables appearing in the state estimation optimization problem. The state trajectory

(gray circles in lower half) is to be reconstructed given the measurements (black circles in upper half)

$$\min_{\chi(0), \omega} V_T(\chi(0), \omega) \quad (4)$$

The solution to the optimization exists for all $T \in \mathbb{I}_{\geq 0}$ under mild continuity assumptions and choice of stage cost. Many choices of (positive, continuous) prior cost $\ell_x(\cdot)$ and stage cost $\ell_d(\cdot)$ are possible, providing a rich class of estimation problems that can be tailored to different applications. Because the system model (1) and cost function (3) are so general, it is perhaps best to start off by specializing them to see the connection to some classical results.

Related Problem: The Kalman Filter

If we specialize to the linear dynamic model $f(x, w) = Ax + Gw$ and $h(x) = Cx$ and let $x(0)$, w , and v be independent, normally distributed random variables, the classic Kalman filter is known to be the statistically optimal estimator, i.e., the Kalman filter produces the state estimate that maximizes the conditional probability of

$x(T)$ given $y(0), \dots, y(T)$. The full information estimator is *equivalent* to the Kalman filter given the linear model assumption and the following choice of quadratic prior and stage costs

$$\begin{aligned} \ell_x(\chi(0), \bar{x}_0) &= (1/2) \|\chi(0) - \bar{x}_0\|_{P_0^{-1}}^2 \\ \ell_d(\omega, v) &= (1/2) \left(\|\omega\|_{Q^{-1}}^2 + \|v\|_{R^{-1}}^2 \right) \end{aligned}$$

where random variable $x(0)$ is assumed to have mean $\bar{x}_0$ and variance P_0 and random variables w and v are assumed zero mean with variances Q and R , respectively. The Kalman filter is also a *recursive* solution to the state estimation problem so that only the current mean $\hat{x}$ and variance P of the conditional density are required to be stored, instead of the entire history of measurements $y(i), i = 0, \dots, T$. This computational efficiency is critical for success in online application for processes with short time scales requiring fast processing.

But if we consider nonlinear models, the maximization of conditional density of $x(T)$ is usually

Moving Horizon Estimation, Fig. 2 Schematic of the moving horizon estimation problem

an intractable problem, especially in online applications. So MHE becomes a natural alternative for nonlinear models or if an application calls for hard constraints to be imposed on the estimated variables.

Moving the Horizon

An obvious problem with solving the full information optimization problem is that the number of decision variables grows linearly with time T , which quickly renders the problem intractable for continuous processes that have no final time. A natural alternative to full information is to consider instead a finite moving horizon of the most recent N measurements. Figure 2 displays this idea. The initial condition $\chi(0)$ is now replaced by the initial state in the horizon, $\chi(T-N)$, and the decision variable sequence of process disturbances is now just the last N variables $\omega = (\omega(T-N), \dots, \omega(T-1))$. Now, the big question remaining is what to do about the neglected, past data. This question is strongly related to what penalty to use on the initial state in the horizon $\chi(T-N)$. If we make this initial state a free variable, that is equivalent to completely discounting the past data. If we wish to retain some of the influence of the past data and keep the moving horizon estimation problem close to the full information problem, then we must choose an appropriate penalty for the initial state. We discuss this problem next.

Arrival cost. When time is less than or equal to the horizon length, $T \leq N$, we can simply do full information estimation. So we assume throughout that $T > N$. For $T > N$, we express the MHE objective function as

$$\hat{V}_T(\chi(T-N), \omega) = \Gamma_{T-N}(\chi(T-N)) + \sum_{i=T-N}^{T-1} \ell_d(\omega(i), v(i))$$

subject to (2). The MHE problem is defined to be

$$\min_{\chi(T-N), \omega} \hat{V}_T(\chi(T-N), \omega) \quad (5)$$

in which $\omega = \{\omega(T-N), \dots, \omega(T-1)\}$ and the hat on $V(\cdot)$ distinguishes the MHE objective function from full information. The designer must now choose this prior weighting $\Gamma_k(\cdot)$ for $k > N$.

To think about how to choose this prior weighting, it is helpful to first think about solving the full information problem by breaking it into *two* nonoverlapping sequences of decision variables: the decision variables in the time interval corresponding to the neglected data ($\omega(0), \omega(1), \dots, \omega(T-N-1)$) and those in the time interval corresponding to the considered data in the horizon ($\omega(T-N), \dots, \omega(T-1)$). If we optimize over the first sequence of variables and store the solution as a function of the terminal state $\chi(T-N)$, we have defined what is known as the arrival cost. This is the optimal cost to arrive at a given state value.

Definition 1 (Arrival cost) The (full information) arrival cost is defined for $k \geq 1$ as

$$Z_k(x) = \min_{\chi(0), \omega} V_k(\chi(0), \omega) \quad (6)$$

subject to (2) and $\chi(k; \chi(0), \omega) = x$.

Notice the terminal constraint that χ at time k ends at value x . Given this arrival cost function, we can then solve the full information problem by optimizing over the remaining decision variables. What we have described is simply the *dynamic*

programming strategy for optimizing over a sum of stage costs with a dynamic model (Bertsekas 1995).

We have the following important equivalence.

Lemma 1 (MHE and full information estimation) *The MHE problem (5) is equivalent to the full information problem (4) for the choice $\Gamma_k(\cdot) = Z_k(\cdot)$ for all $k > N$ and $N \geq 1$.*

Using dynamic programming to decompose the full information problem into an MHE problem with an arrival cost penalty is conceptually important to understand the structure of the problem, but it doesn't yet provide us with an implementable estimation strategy because we cannot compute and store the arrival cost when the model is nonlinear or other constraints are present in the problem. But if we are not too worried about the optimality of the estimator and are mainly interested in other properties, such as stability of the estimator, we can find simpler design methods for choosing the weighting $\Gamma_k(\cdot)$. We address this issue next.

Estimator Properties: Stability

An estimator is termed *robustly stable* if small prior errors $x(0) - \bar{x}_0$ and small disturbances (w, v) lead to small estimate errors proportional to the size of (w, v) . Even in the case of the Kalman filter for linear systems, estimator optimality is insufficient to guarantee stability. For linear systems, there exists a stable estimator only if the system is *detectable*. The Kalman filter is one such estimator, but statistical optimality is not required for (robust) stability, and there are many Luenberger observers that are robustly stable. For nonlinear systems, one popular form of detectability is called *incremental input/output-to-state stability (i-IOSS)* (Sontag and Wang 1997). A property stronger than detectability is *observability*. A system is observable if its initial state can be reconstructed from a finite number of measurements. Precise definitions of these terms are available elsewhere (Rawlings et al. 2017, Ch. 4), but these basic notions are sufficient for this overview.

Since there are suboptimal estimators that nevertheless are robustly stable for detectable linear systems, we can hope that there are also such estimators for nonlinear systems. Because even the more modest goal of making MHE equivalent to FIE appears out of reach, we examine the circumstances in which MHE is robustly stable. The simplest case is when the system is observable. Leaving aside certain technicalities, MHE using the flat prior $\Gamma_k(\cdot) = 0$ is robustly stable if a system is observable. However, we may significantly compromise estimation accuracy if we ignore past data completely.

Here, we are faced with a situation embarrassing to the current state of theory: there is no general proof that FIE (and, as a result, MHE with the arrival cost as prior penalty) is robustly stable in the presence of bounded disturbances, i.e., persistent small disturbances. It is known that FIE is both robustly stable and convergent when the disturbances converge to zero quickly enough (Rawlings and Ji 2012) and in the special case of exponential detectability and a restrictive choice of stage cost (excluding least-squares objectives) in the presence of bounded disturbances (Knüfer and Müller 2018). Even more perplexing is that there are conditions that guarantee the robust stability of MHE in the case of exponential detectability while (potentially) permitting a least-squares objective (Müller 2017; Allan and Rawlings 2019). Unfortunately, these conditions are not well understood and difficult to verify, and thus do not yet shed much light on practical design considerations. In the case of convergent disturbances, we can achieve robust stability of MHE by choosing $\Gamma_k(\cdot)$ both positive-definite and *smaller* than the arrival cost, as shown in Fig. 3 (Rawlings et al. 2017, Theorem 4.25).

Related Problem: Statistical Sampling

MHE is based on optimizing an objective function that bears some relationship to the conditional probability of the state trajectory given the measurements. As discussed in the section on the Kalman filter, if the system is linear with

Moving Horizon Estimation, Fig. 3 Arrival cost $Z_k(x)$, underbounding prior weighting $\Gamma_k(x)$, and MHE optimal value $\hat{V}_k^0$, for all x and $k > N$, $Z_k(x) \geq \Gamma_k(x) \geq \hat{V}_k^0$, and $Z_k(\hat{x}(k)) = \Gamma_k(\hat{x}(k)) = \hat{V}_k^0$

normally distributed noise, this relationship can be made exact, and MHE is therefore an optimal statistical estimator. But in the nonlinear case, the objective function is chosen with engineering judgment and is usually only a surrogate for the conditional probability. By contrast, sampling methods such as particle filtering are designed to sample the conditional density also in the nonlinear case. The mean and variance of the samples then provide estimates of the mean and variance of the conditional density of interest. In the limit of infinitely many samples, these methods are exact. The efficiency of the sampling methods depends strongly on the model and the dimension of the state vector n , however. The efficiency of the sampling strategy is particularly important for online use of state estimators. Rawlings and Bakshi (2006) and Rawlings and Mayne (2009, pp. 329–355) provide some comparisons of particle filtering with MHE.

Another downside of the particle filtering methods covered in those sources is that, as time goes on, particles can drift out of areas with high probability density. These low-weight particles contribute little to the state estimate and variance, leading to a small number of particles with large weights to determine these quantities. Resampling can mitigate this problem, but it does not solve it. A better method is the

feedback particle filter proposed in Yang et al. (2014). There, a control law is used to move particles as part of the Bayesian update step of the filter, which helps keep them in regions of high probability density.

Numerical Implementation

MHE is implemented by solving a series of nonlinear programs. In principle, any nonlinear programming method can be used, but the problem has a sparse structure that can be exploited by suitable solvers. Several open-source packages that exist, together, permit users to quickly implement MHE without detailed knowledge of the underlying numerical methods. IPOPT (Wächter and Biegler 2006) is an interior-point solver, CasADi (Available online at casadi.org) is a symbolic framework that provides algorithmic (automatic) differentiation and interfaces to optimization packages, and MPCTools (Available online at www.bitbucket.org/rawlings-group/octave-mpctools) provides a high-level interface to CasADi and IPOPT. Several examples of MHE problems implemented with these tools are available online (www.engineering.ucsb.edu/~jbrow/mpc/figures.html).

Summary and Future Directions

MHE is one of the few state estimation methods that can be applied to general nonlinear models for which properties such as estimator stability can be established (Rawlings et al. 2017; Rao et al. 2003). The required online solution of an optimization problem is computationally demanding in some applications but can provide significant benefits in estimator accuracy and rate of convergence (Patwardhan et al. 2012). Current topics for MHE theoretical research include proving robust stability of FIE in the presence of bounded disturbances, seeking better understanding about the conditions under which MHE is robustly stable, and establishing properties of suboptimal MHE. For example, Alessandri et al. (2008) analyze a simplified form of MHE where

the ω decision variables of (4) are neglected and show that terminating within a specified tolerance of optimality preserves the boundedness and stability of the estimate error. Although encouraging that strict optimality is not required, the challenge with using this style of suboptimal MHE is that because the tolerance is given from the *global* solution, a global solver must still be used online to satisfy this requirement. The current main focus for MHE applied research involves reducing the online computational complexity to reliably handle challenging large-dimensional, nonlinear applications (Zavala et al. 2008; Zavala and Biegler 2009; Kühl et al. 2011; López-Negrete and Biegler 2012; Wynn et al. 2014).

Abstract

The area of multiagent reinforcement learning (MARL) provides a promising approach to learning collaborative policies for multiagent systems. However, MARL is inherently more difficult than single-agent learning problems because agents interact with both the environment and other agents. Specifically, learning in multiagent settings involves significant issues of the nonstationary, equilibrium selection, credit assignment, and curse of dimensionality. Despite these difficulties, there have been important recent developments in MARL. This entry provides a background in multiagent reinforcement learning as well as an overview of recent work on topics of game theory, communication, coordination, knowledge sharing, and agent modeling. This entry also summarizes several useful multiagent simulation platforms.

Introduction

The area of multiagent reinforcement learning (MARL) investigates how a group of artificial intelligence (AI) agents can learn to cooperate and coordinate at the level of human experts. MARL presents several benefits over a single-agent learning approach, including (1) improved robustness because the failure of a single agent could be addressed by another agent; (2) improved efficiency, since a complicated task can be divided into simpler sub-tasks, distributed across agents, and then solved simultaneously; and (3) improved scalability, because new agents can easily be added to the decentralized collaboration in MARL. These advantages increase the appeal of MARL in numerous applications, including robot manufacturing, traffic control, and network routing.

Learning in a multiagent setting is inherently more difficult than single-agent learning problems, in particular because agents interact with both the environment and the other agents (Buşoniu et al. 2010). One crucial challenge is the difficulty of learning optimal policies in the presence of changing policies of the other learning agents whose concurrent actions affect the team-wide performance (Omidshafiei et al. 2017; Tuyls and Weiss 2012; Hernandez-Leal et al. 2017). Therefore, a small change in one agent's policy may result in large, unpredictable changes in the policies of fellow agents. The difficulty of learning in MARL is further complicated by the challenges of multiagent credit assignments (han Chang et al. 2004; Foerster et al. 2017), the high dimensionality of the problems (Yang et al. 2018), and the lack of convergence guarantees (Bowling 2005; Nowe et al. 2012). There have been several important recent developments in MARL, from integration of game-theoretic concepts to new deep learning methods.

Background

Framework

There are several frameworks introduced in this section which can be used to represent learning in MARL settings.

Normal Form Games

Interactions between multiple agents can be represented by a normal form game. Formally, a normal form game is defined as a tuple $\langle \mathcal{I}, \mathcal{A}, \mathcal{R} \rangle$ (Leyton-Brown and Shoham 2008); $\mathcal{I} = \{1, \dots, n\}$ is the set of n agents (also referred to as players); $\mathcal{A} = \{\mathcal{A}^1, \dots, \mathcal{A}^n\}$ is the set of available actions for each agent; and $\mathcal{R} = \{\mathcal{R}^1, \dots, \mathcal{R}^n\}$ is the set of reward functions, where $i \in \mathcal{I}$ and $\mathcal{R}^i : \mathcal{A}^1 \times \dots \times \mathcal{A}^n \rightarrow \mathbb{R}$ is a reward function for agent i according to the payoff table (e.g., Table 1). Joint sets are typeset in bold throughout the paper for clarity.

In a normal form game, each agent i selects an action a^i from its strategy $\sigma^i : \mathcal{A}^i \rightarrow [0, 1]$, where σ^i outputs the probability of taking any given action in the action set. Then, agent i receives its utility based on a joint action $\mathbf{a} = \{a^1, \dots, a^n\}$ and its reward function (i.e., $r^i = \mathcal{R}^i(\mathbf{a})$). For instance, with the payoff table shown in Table 1, if agent 1's strategy chooses action x (i.e., $a^1 = x$) and agent 2's strategy chooses action y (i.e., $a^2 = y$), then the joint action is $\mathbf{a} = \{x, y\}$, and agents 1 and 2 receive a reward of 0 and 10, respectively. Each agent i has an objective to maximize its *expected* utility: $\sum_{\mathbf{a} \in \mathbb{A}} \prod_{j=1}^n \sigma^j(a^j) R^i(\mathbf{a})$. Note that the utility depends on the other agents' actions, and thus the expected utility is affected by other agents' strategies. Therefore, agents must consider the strategies of others in order to maximize their expected utilities.

Markov Games

The normal form game framework assumes the environment is static, so it is not suitable for problems in which agents are making sequential decisions in an environment where there is a state transition function. A Markov game (Littman 1994) provides a more general framework than a normal form game based on the Markov

Multiagent Reinforcement Learning, Table 1

Example payoff table of the prisoner's dilemma. Each agent chooses to either cooperate and stay silent (x) or betray and confess their crime (y)

		Agent 2	
Agent 1		x	y
	x	(5, 5)	(0, 10)
	y	(10, 0)	(1, 1)

decision process (MDP). Formally, a Markov game is defined as a tuple $\langle \mathcal{I}, \mathcal{S}, \mathcal{A}, \mathcal{R}, \mathcal{T}, \gamma \rangle$; $\mathcal{I} = \{1, \dots, n\}$ is the set of n agents; $\mathcal{S}$ is the set of states; $\mathcal{A} = \{\mathcal{A}^1, \dots, \mathcal{A}^n\}$ is the set of action spaces for all n agents; $\mathcal{R} = \{\mathcal{R}^1, \dots, \mathcal{R}^n\}$ is the set of reward functions for all n agents; $\mathcal{T} : \mathcal{S} \times \mathcal{A}^1 \times \dots \times \mathcal{A}^n \mapsto \mathcal{S}$ is the transition function; and $\gamma \in [0, 1]$ is the discount factor. At each timestep t , each agent i executes an action according to its stochastic policy $a_t^i \sim \pi^i(s_t; \theta^i)$ parameterized by θ^i , where $s_t \in \mathcal{S}$. A joint action $\mathbf{a}_t = \{a_t^1, \dots, a_t^n\}$ yields a transition from current state s_t to next state $s_{t+1} \in \mathcal{S}$ with probability $\mathcal{T}(s_{t+1} | s_t)$. Agent i then obtains a reward according to the function $r_t^i = \mathcal{R}^i(s_t, \mathbf{a}_t, s_{t+1})$. Each agent has an objective to maximize its expected cumulative reward or value function. Specifically, given an initial state s_0 and current joint policy $\{\pi^1, \dots, \pi^n\}$, a value function at the initial state for agent i is given by $V^i(s_0) = \mathbb{E}[\sum_t \gamma^t r_t^i | s_0, \pi^1, \dots, \pi^n]$. As in normal form games, the value function depends on other agents' current policies. Because agents are independently updating their policies in MARL, the dependency in the value function leads to the challenge of non-stationarity (see Section “Challenges”). Note that a Markov game reduces to an MDP (or a normal form game) if there is only a single agent (or a single state) (Nowe et al. 2012).

Decentralized Partially Observable MDP (Dec-POMDP)

Dec-POMDPs Oliehoek and Amato (2016) are a special case of Markov games in which agents have equivalent reward functions (i.e., shared team reward), but do not have direct access to the state. At each time step t , each agent can

partially observe the state by receiving observation $o_t^i \in \Omega^i$ with joint observation probability $\mathcal{O}(\mathbf{o}_t, s_{t+1}, \mathbf{a}_t) = P(\mathbf{o}_t | s_{t+1}, \mathbf{a}_t)$, where Ω^i is a finite set of observations available to agent i , $\mathbf{o}_t = \{o_t^1, \dots, o_t^n\}$, and $\mathcal{O}$ is the observation function representing the probability of observing $\mathbf{o}_t$ conditioned on agents executing $\mathbf{a}_t$ and the state transitioning to s_{t+1} . In this case, agent i selects an action based on its observation history $h_t^i: a_t^i \sim \pi^i(h_t^i; \theta^i)$, where $h_t^i = \{o_0^i, \dots, o_t^i\}$.

Meta Games

A meta game (also referred to as an empirical game) (Tuyls et al. 2018; Ponsen et al. 2009) is a simplified model of a multiagent system. In a meta game, only relevant meta-strategies, or styles of play, that are played empirically are considered, instead of the entire primitive strategies. For example, in a game of poker, possible meta-strategies are {"aggressive," "tight," "passive"}.

Challenges

Non-stationarity

In MARL, multiple agents concurrently learn and interact in a shared environment (Buşoniu et al. 2010). From the perspective of agent i , the value of a state s estimated at a learning time t_1 may not match the value of the same state estimated at a different learning time t_2 (i.e., $V_{t_1}^i(s) \neq V_{t_2}^i(s)$) due to the possibility that other agents could have different policies as a result of learning (i.e., $\{\pi_{t_1}^1, \dots, \pi_{t_1}^n\} \neq \{\pi_{t_2}^1, \dots, \pi_{t_2}^n\}$). This leads to the environment being perceived as nonstationary by individual agents, rendering the Markov property invalid (Tesauro 2004). This problem is also referred to as the *moving-target* problem (Tuyls and Weiss 2012).

Equilibrium Selection

The concept of an optimal solution may not exist in some multiagent settings. An alternative solution concept is an equilibrium among agent strategies, such as a Nash equilibrium (Leyton-Brown and Shoham 2008; Nowe et al. 2012). Furthermore, multiple equilibria can exist in MARL (Nowe et al. 2012) (e.g., two Nash equilibria exist in Table 1: $\{x, x\}$ and $\{y, y\}$).

The challenge then is to converge to a better equilibrium with higher expected utility or return. This equilibrium selection, however, is often intractable (e.g., when the agents' action spaces are large or continuous) (Omidshafiei et al. 2019; Goldberg et al. 2010; Avis et al. 2010).

Credit Assignment

In cooperative MARL settings, joint actions often generate shared rewards, such that $\mathcal{R}^1(s_t, \mathbf{a}_t, s_{t+1}) = \dots = \mathcal{R}^n(s_t, \mathbf{a}_t, s_{t+1})$ for all agents. As they all receive the same reward, it is difficult for each agent to identify its own contribution to the team's performance. This makes coordination difficult, even with small numbers of agents (han Chang et al. 2004; Foerster et al. 2017).

Curse of Dimensionality

As the number of agents increases, the most straightforward issue with learning is the exponentially increasing state/action space. The credit assignment problem also becomes increasingly more difficult with more agents due to greater noise from the increased number of agent interactions and exploratory actions being taken at any given time (Yang et al. 2018). To illustrate this idea, consider four agents learning in a discrete, 4×4 gridworld. While this domain might seem small, it has the equivalent state space complexity to a 256×256 gridworld for a single-agent problem (a 6×6 multiagent problem has the equivalent scaling to a 1296×1296 single-agent problem).

Current Research Topics in MARL

Game Theory

One important solution concept in game theory is the Nash equilibrium in which each agent acts with its best response to the current strategies of the other agents (Leyton-Brown and Shoham 2008). A number of approaches use the Nash equilibrium as a solution concept for MARL. For example, *policy-space response oracles* (PSRO) (Lanctot et al. 2017) incrementally build a policy by finding the best response to

the meta-strategies of the other players. An extension, called *deep cognitive hierarchies* (DCH), approximates PSRO by searching for a fixed number of epochs (in contrast to the unbounded number of epochs in PSRO). PSRO/DCH are evaluated on 2D gridworld games and Leduc poker, (Leduc poker is a toy poker game often used as a benchmark in Poker AI research. See Southey et al. (2012) for more information.) which show convergence to an approximate Nash equilibrium.

Dynamical multiagent systems, however, are not guaranteed to converge to a Nash equilibrium (Omidshafiei et al. 2019). To address this issue, *Markov-Conley Chains* (MCCs) have been introduced as a new game-theoretic solution concept that is capable of capturing the evolutionary dynamics of multiagent interactions. The α -Rank method utilizes MCCs to evaluate and rank agents in large-scale dynamical systems and has been empirically validated in several domains, such as AlphaZero Chess and Leduc Poker (Omidshafiei et al. 2019).

Learning Communication

Communication between agents has an essential role in accomplishing multiagent tasks, but it is often difficult to specify an appropriate communication protocol. Recent work has shown that agents can learn and use a communication protocol to solve a coordinated task. For instance, *reinforced inter-agent learning* (RIAL) (Foerster et al. 2016) learns a discrete and finite set of communication messages. Each agent outputs Q-values for the environment and communication actions, and they then use their observations and received messages to make their decisions. Because agents in RIAL are assumed to be homogeneous, learning is simplified via parameter sharing in which all agents simultaneously train a single policy. Despite learning a single policy, agents can still learn specialized behaviors that are based on different initial conditions, observations, or relative formations (Panait and Luke 2005). *Differentiable inter-agent learning* (DIAL) (Foerster et al. 2016) introduces the idea of agents providing feedback about received messages by sending gradients across

the communication channel. Experiments on coordinated tasks show that the integration of this feedback in DIAL leads to a better performance than both RIAL and a no-communication baseline. An alternative, called *communication neural nets* (CommNets) (Sukhbaatar et al. 2016), sends continuous messages between agents. Each agent takes the form of either multilayer neural networks or long short-term memory networks (LSTMs) (Hochreiter and Schmidhuber 1997), (long short-term memory (LSTM) networks (Hochreiter and Schmidhuber 1997) are one type of recurrent neural network (RNN). LSTMs are well-suited for identifying long-term temporal dependencies by augmenting information in the cell state.) and the message is constructed by taking the average of the outputs among internal states in neural networks.

Learning Coordination

The learning of cooperative behaviors can be achieved without the explicit involvement of communication. For example, *multiagent deep deterministic policy gradient* (MADDPG) (Lowe et al. 2017) proposes actor-critic policy gradient methods with decentralized actors and centralized critics. During training, centralized critics receive additional information about the other agents (i.e., agents' policies, observations, and actions) and compute *joint* Q-values. As a result, the environment is stationary from the perspective of the centralized critics, which has been shown to significantly improve the stability of the multiagent learning. The critic is only necessary during the learning process, and since the actors only use local information during both training and execution, the system is considered to be decentralized during execution. MADDPG has demonstrated success in both collaborative and competitive tasks, and it has been evaluated in particle environments at various levels of complexity (see Section “Domains of MARL”).

Another related research direction is based on population-based training (PBT). PBT Jaderberg et al. (2017) is an online evolutionary process that optimizes hyperparameters by replacing underperforming agents with well-performing agents and adding noise (called mutation)

between the optimization steps. PBT is extended to multiagent settings in the *for the win* (FTW) framework (Jaderberg et al. 2018) in which a population of 30 agents is used to learn collaborative behaviors. FTW agents use a two-tiered hierarchical structure of recurrent neural networks (RNNs) (RNNs are a type of network that incorporates feedback, allowing the network to process sequences of data.) that operate on different time scales, improving their ability to utilize memory and learn temporally consistent strategies. FTW recently demonstrated “above human-level performance” in a 2 versus 2 capture the flag challenge in the video game, Quake III Arena (id Software).

Knowledge Sharing

Agents typically develop individualized knowledge of a domain as a result of executing some type of stochastic exploration of the environment. Similar to human social groups, the collective intelligence of MARL agents may be improved if the agents share what they have individually learned. Several frameworks allow a wide variety of methods to transfer different types of knowledge (Taylor and Stone 2009; Wadhwanian et al. 2019). One approach to transferring knowledge is via action advising in which an experienced “teacher” agent helps a less experienced “student” agent by suggesting which action to take next. For example, the recent *Learning to Coordinate and Teach Reinforcement* (LeCTR) framework (Omidshafiei et al. 2018) learns teacher policies that indicate both when and which actions to advise. LeCTR shows improved team-wide learning performance compared to prior teaching methods that advise using a variety of teaching heuristics (Amir et al. 2016; Clouse 1997; da Silva et al. 2017; Torrey and Taylor 2013). *Hierarchical multiagent teaching* (HMAT) (Kim et al. 2019) extends LeCTR to learn teacher policies with deep hierarchical reinforcement learning (RL). HMAT shows improved learning performance in difficult tasks involving high-dimension state-action spaces for problems with long time horizons.

The *distillation with value matching* (DVM) (Wadhwanian et al. 2019) approach accomplished

knowledge sharing between homogeneous agents by exploiting the fact that teams of homogeneous agents have the inherent property of being interchangeable within the same environment (Zinkevich and Balch 2001). In particular, DVM creates a new distilled policy that combines knowledge learned from all agents by minimizing the Kullback-Leibler divergence of the policy with respect to all agents’ policies. Additionally, the centralized critics in DVM are trained such that they output an identical Q-value invariant to the ordering of inputs (a process referred to as value matching). Value matching is shown to be a necessary step to reflect the new Q-value with the distilled policy and enables continued learning without forgetting of the information that has been distilled.

Agent Modeling

It is typically necessary for an agent in a multiagent system to be able to predict the intent of the other agents and then respond accordingly. However, if, in contrast to the centralized training approaches, agents cannot share full policies with one another (e.g., due to privacy concerns), agents can instead develop models of the other agents to predict their strategies. *Deep reinforcement opponent network* (DRON) (He et al. 2016) learns representations of other agents’ policies and incorporates them into a joint Q-function. A second approach by Grover et al. (Grover et al. 2018) aims to learn representations of agent policies using an unsupervised encoder-decoder framework. An encoder is used to learn a mapping from episodes (i.e., a sequence of observation and action pairs) to continuous embeddings, which are then mapped to a distribution over actions of the agent being modeled using a learned decoder. Experiments show that the learned embeddings are generalizable and can even be used to represent unseen agents. Inferring other agents’ policies is often useful, but for some domains/tasks, other information might also need to be inferred. For example, *Theory of Mind neural network* (ToMnet) (Rabinowitz et al. 2018) learns to predict an agent’s characteristics and internal states, such as action probabilities,

probabilities of certain objects being used, and successor representations (Dayan 1993).

Domains of MARL

Evaluating new algorithms is an essential part of research on MARL. This section highlights numerous multiagent evaluation platforms and provides links to code if they are open source.

Multiagent Particle Environment

This environment provides a simple multiagent environment with basic simulated physics, such as collision, speed, and acceleration. The observation space is continuous, and the action space can be either discrete or continuous. Several scenarios are provided within the environment. These scenarios include cooperative navigation, where agents learn to cover all landmarks; predator–prey, where multiple predators learn to collaborate to catch prey; and cooperative communication, where a speaker agent communicates to guide a listener agent. MADDPG (Lowe et al. 2017) uses the environment to show both collaborative and competitive behaviors. Researchers can create their own environments, and open-sourced code is available at <https://github.com/openai/multiagent-particle-envs>.

MAgent

MAgent provides a large-scale platform that can support many (e.g., hundreds of) agents. Three environments, pursuit, gathering, and battle, are provided, but researchers can use the platform to design customized environments/agents. Open-sourced code is available at <https://github.com/geek-ai/MAgent>.

MuJoCo

MuJoCo is a physics engine that provides accurate simulations for robotic applications Todorov (2012). Single-agent MuJoCo environments have gained popularity, and they are often used for benchmarking and comparing RL algorithms. Several competitive multiagent domains have recently been introduced, including the 2 vs. 2

soccer game (Liu et al. 2019). Open-sourced code for single-agent environments is provided at <https://gym.openai.com/envs/#mujoco>. Open-sourced code for multiagent environments is provided at <https://github.com/openai/multiagent-competition> and https://github.com/deepmind/dm_control/tree/master/dm_control/locotion/soccer.

StarCraft II

StarCraft II is a strategy video game in which a player must collect resources, build structures, and gather combat units to win against an opponent player (for the case of a 1 vs. 1 tournament). StarCraft II is one of the “grand challenges” for AI research because algorithms must overcome several difficult obstacles, such as long-term planning, large action spaces, and imperfect information. Recently, AlphaStar (Vinyals et al. 2019) developed by DeepMind has beaten professional human players. A basic StarCraft II learning environment is provided at <https://github.com/deepmind/pysc2>.

Dota 2

The video game of Dota 2 is another grand challenge for AI research. Dota 2 is a strategy game played between two teams of five players. The five players must collaborate and win against an opponent team. Similar to StarCraft II, Dota 2 has difficult challenges, including long time horizons, high-dimensional observation/action spaces, and partially observed states. The algorithm developed by the OpenAI Five project has defeated professional human teams (OpenAI 2018).

Conclusion and Future Directions

Multiagent reinforcement learning is a promising approach to learning collaborative policies for multiagent systems. However, learning in multiagent settings is difficult due to the issues of non-stationarity (Omidshafiei et al. 2017; Tuyls and Weiss 2012; Hernandez-Leal et al. 2017), equilibrium selection (Omidshafiei et al. 2019; Goldberg et al. 2010; Avis et al. 2010), credit

assignment (han Chang et al. 2004; Foerster et al. 2017), and high-dimensional state spaces (Yang et al. 2018). Despite these difficulties, there have been important recent developments in MARL. This entry has provided an overview of recent work on topics of game theory, communication, coordination, knowledge sharing, and agent modeling (see Section “Current Research Topics in MARL”). This entry has also introduced several extremely useful multiagent simulation platforms (see Section “Domains of MARL”).

There are many open research questions in MARL. For example, it is unclear how existing learning methods can be extended to environments with heterogeneous agents and/or problems in which agents have different observation/action spaces and capabilities. Another important question is fast adaptation in MARL. An ideal agent should be able to adapt quickly to changing teammates, opponents, and environments. However, the existing MARL algorithms are sample inefficient and require thousands of experiences to adapt to the changes. Combining meta-learning approaches (Meta-learning trains a model on a variety of tasks, such that it can learn new skills or adapt to new environments quickly using only a small number of training samples (e.g., learning of initial model parameters (Finn et al. 2017)).) with MARL is one promising future direction to pursue.

Abstract

One starting point for the analysis and design of a control system is the block diagram representation of a plant. Since it is nontrivial to convert a physical model of a plant into a block diagram, this can be performed manually only for small plant models. Based on research from the last 40 years, more and more mature tools are available to achieve this transformation fully automatically. As a result, multi-domain plants, for example, systems with electrical, mechanical, thermal, and fluid parts, can be modeled in a unified way and can be used directly as input–output blocks for control system design. An overview of the basic principles of this approach is given, and it is shown how to utilize nonlinear, multi-domain plant models directly in a controller. Finally, the low-level “Functional Mockup Interface” standard is sketched to exchange multi-domain models between many different modeling and simulation environments.

Introduction

Methods and tools for control system analysis and design usually require an input–output block

diagram description of the plant to be controlled. Apart from small systems, it is nontrivial to derive such models from first principles of physics. Since a long time, methods and tools are available to construct such models automatically for one domain, for example, a mechanical model, an electronic, or a hydraulic circuit. These domain-specific methods and tools are, however, only of limited use for the modeling of multi-domain systems.

In the dissertation (Elmqvist 1978), a suitable approach for multi-domain, object-oriented modeling has been developed by introducing a modeling language to define models on a high level based on first principles. The resulting differential-algebraic equation (DAE) systems are automatically transformed with proper algorithms in a block diagram description with input and output signals based on ordinary differential equations (ODEs), where the algebraic variables have been eliminated and all derivatives are explicitly solved for.

In 1978, computers were not powerful enough to apply this method on systems with more as a few hundred equations. In the 1990s the technology has been substantially improved, many different modeling languages appeared (and also disappeared), and object-oriented modeling was introduced in commercial simulation environments.

In Table 1, an overview of the most important standards, languages, and tools in the year 2019 for multi-domain modeling is given:

- The *Modelica* language is a standard from the Modelica Association (2017). The first version was released in 1997. The language is accompanied with the *Modelica Standard Library* (<https://github.com/modelica/ModelicaStandardLibrary>) – an open-source Modelica library with about 1600 model components and 1350 functions from many domains. There are several free and commercial software tools supporting the Modelica language and the Modelica Standard Library.
- The *VHDL-AMS* language is a standard from IEEE (IEEE 1076.1-2017 2017), first released in 1999. It is an extension of the widely used

VHDL hardware description language. This language is especially used in the electronics community.

- There are several (proprietary) vendor-specific modeling languages, notably *EcosimPro* and *gRPOMS* for modeling of thermodynamic processes, *Simscape* from MathWorks as an extension to Simulink®, *MAST* the underlying modeling language of *Saber* (Mantooth and Vlach 1992), and the language of *20-sim*, which supports *bond graphs* (Karnopp et al. 2012). Bond graphs are a special graphical notation to define multi-domain systems based on energy flows. It was invented in 1959 by Henry M. Paynter.
- *Modia* and its supporting packages form an open-source prototyping platform based on the *Julia* programming language (Bezanson et al. 2017). *Modia* is the name of a *Julia* package that supports a modeling language called “*Modia language*” as a domain-specific extension of *Julia* and provides algorithms to symbolically transform *Modia* models into DAE systems that can be numerically solved by standard DAE integrators. The *Modia* language and the new algorithms used in the *Modia* package are intended as inspiration for the development of the next *Modelica* generation.

In section “[Modeling Language Principles](#)”, the principles of multi-domain modeling based on a modeling language are summarized. In section “[Models for Control Systems](#)”, it is shown how such models can be used not only for simulation but also as components in nonlinear control systems. Finally, in section “[The Functional Mockup Interface](#)”, an overview about a low-level standard for the exchange of multi-domain systems is described.

Modeling Language Principles

Schematics: The Graphical View

Modelers nowadays require a simple to use graphical environment to build up models. With very few exceptions, multi-domain environments

define models by schematic diagrams. A typical example is given in Fig. 1, showing a simple direct current electrical motor in Modelica.

In the lower left part, the electrical circuit diagram of the DC motor is visible, consisting mainly of the armature resistance and inductance of the motor, a voltage source, and component “emf” to model in an idealized way the electromotoric forces in the air gap. On the lower right part, the motor inertia, a gear box, and a load inertia are present. In the upper part, the heat transfer of the resistor losses to the environment is modeled with lumped elements.

A component, like a resistor, rotational inertia, or convective heat transfer, is shown as an icon in the diagram. On the border of a component, small

rectangular or circular signs are present representing the “physical ports.” Ports are connected by lines and model the (idealized) physical or signal interaction between ports of different components, for example, the flow of electrical current or heat or the rigid mechanical coupling. Components are built up hierarchically from other components. On the lowest level, components are described textually with the respective modeling language (see section “[Component Equations](#)”).

Coupling Components by Ports

The ports define how a component can interact with other components. A port contains a definition of the variables that describe the interface and defines in which way a tool can automatically

construct the equations for the connections. A typical scenario is shown in Fig. 2 where the ports of the three components A, B, C are connected together at one point P.

When cutting away the connection lines, the resulting system consists of three decoupled components A, B, C and a new component around P describing the infinitesimally small connection point. The balance equations and the boundary conditions of the respective domain must hold at all these components. When drawing the connection lines, enough information must be available in the port definitions so that the tool can construct the equations of the infinitesimally small connection points automatically.

To summarize, the component developer is responsible that the balance equations and boundary conditions are fulfilled for every component (A, B, C in Fig. 2), and the tool is responsible that the balance equations and boundary conditions are also fulfilled at the points where the components are connected together (P in Fig. 2). As a consequence, the balance equations and boundary conditions are fulfilled in the overall model containing all components and all connections.

Multi-domain Modeling and Simulation, Fig. 2 Cutting the connections around the connection point P results in three decoupled components A, B, C and a new component around P describing the infinitesimally small connection point

In order that a tool can automatically construct the equations at a connection point, every port variable needs to be associated to a port variable type. In Table 2, some port variable types of Modelica are shown. Hereby it is assumed that $u_1, u_2, \dots, u_n, y, v_1, v_2, \dots, v_n, f_1, f_2, \dots, f_n,$

$s_1, s_2, \dots, s_n$ are corresponding port variables from different components that are connected together at the same point P.

Port variable types “input” and “output” define the usual signal connections in block diagrams. “Potential variables” and “flow variables” are used to define standard physical connections. For example, an electrical port contains the electrical potential and the electrical current at the port, and when connecting electrical ports together, the electrical potentials are identical, and the sum of the electrical currents is zero; see Table 2. These equations correspond exactly to Kirchhoff’s voltage and current laws. “Stream variables” are used to describe the connection semantics of intensive quantities in bidirectional fluid flow, such as specific enthalpy or mass fraction. Here, the idealized balance equation at a connection point states, for example, that the sum of the port enthalpy flow rates is zero and the port enthalpy flow rate is computed as the product of the mass flow rate (a flow variable f_i) and the directional specific enthalpy s_i , which is either the (yet unknown) mixing-specific enthalpy s_{mix} when the flow is from the connection point to the port or the specific enthalpy s_i in the port when the flow is from the port to the connection point. More details and explanations are available from Franke et al. (2009). In Table 3 some of the port definitions are shown that are provided by the Modelica Standard Library and the PlanarMechanics library.

Component Equations

Implementing a component in a modeling language means to define the ports of the component and to provide the equations describing the rela-

tionships between the port variables. For example, an electrical capacitor with constant capacitance C can be defined by the equations in the right side of Fig. 3.

Such a component has two ports, the pins “p” and “n,” and the port variables are the electrical currents i_p, i_n flowing into the respective ports and the electrical potentials v_p, v_n at the ports. The first component equation states that if the current i_p at port “p” is positive, then the current i_n at port “n” is negative (therefore, the current flowing into “p” is flowing out of “n”). Furthermore, the two remaining equations state that the derivative of the difference of the port potentials is proportional to the current flowing into port “p.”

One important question is how many equations are needed to describe such a component? For an input–output block, the answer is simple: all input variables are known, and for all other variables, one equation per unknown is needed. Counting equations for physical components, such as a capacitor, are more involved: the requirement that *any type of component connections shall always result in identical numbers of unknowns and equations of the overall system* leads to the following counting rule (for a proof, see Olsson et al. 2008):

- 1. The number of potential and the number of flow variables in a port must be identical.
- 2. Input variables and variables that appear differentiated are treated as known variables.
- 3. The number of equations of a component must be equal to the number of unknowns minus the number of flow variables.

Multi-domain Modeling and Simulation, Table 2 Some port variable types in Modelica

Port variable type	Connection semantics
Input variables u_i , output variable y	$u_1 = u_2 = \dots = u_n = y$ (exactly one output variable can be connected to n input variables)
Potential variables v_i	$v_1 = v_2 = \dots = v_n$
Flow variables f_i	$0 = \sum f_i$
Stream variables s_i (with associated flow variables f_i)	$0 = \sum f_i \hat{s}_i; \hat{s}_i = \begin{cases} s_{\text{mix}} & \text{if } f_i > 0 \\ s_i & \text{if } f_i \leq 0 \end{cases}$ ($0 = \sum f_i$)

Multi-domain Modeling and Simulation, Table 3

Multi-domain Modeling and Simulation, Fig. 3 Equations of a capacitor component

In the example of the capacitor, there are five unknowns (i_p , i_n , v_p , v_n , du/dt) and two flow variables (i_p , i_n). Therefore, $5 - 2 = 3$ equations are needed to define the component in Fig. 3.

Modeling languages are used to provide a textual description of the ports and of the equations in a specific syntax. For example, in Modelica the capacitor from Fig. 3 can be defined as shown in Fig. 4 (keywords of the language are written in boldface). In VHDL-AMS the capacitor model can be defined as shown in Fig. 5.

One difference between Modelica and VHDL-AMS is that in Modelica, all equations need to be explicitly given, and port variables (such as $p.i$) can be directly accessed in the model (Fig. 4). Instead, in VHDL-AMS (and some other modeling languages), port variables cannot be accessed in a model, and instead via the “**quantity .. across .. through .. to ..**” construction, the relationships between the port variables are implicitly defined and correspond to the Modelica equations “ $0 = p.i + n.i$ ” and “ $u = p.v - n.v$ ”.

Simulation of Multi-domain Systems

Collecting all the component equations of a multi-domain system model together with all connection equations results in a DAE system:

$$\mathbf{0} = \mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{w}, \mathbf{y}, \mathbf{u}, t) \quad (1)$$

where $t \in \mathbb{R}$ is time, $\mathbf{x}(t) \in \mathbb{R}^{n_x}$ is a vector which contains variables that appear differenti-

ated, $\mathbf{w}(t) \in \mathbb{R}^{n_w}$ is a vector of algebraic variables, $\mathbf{y}(t) \in \mathbb{R}^{n_y}$ is a vector of output variables, $\mathbf{u}(t) \in \mathbb{R}^{n_u}$ is a vector of input variables, and $\mathbf{f} \in \mathbb{R}^{n_x+n_w+n_y}$ is a vector of functions that represent the right-hand sides of the equations of the DAE system. The equations in (1) can be solved numerically with an integrator for DAE systems; see, for example, Brenan et al. (1996). For DAEs that are linear in their unknowns, a complete theory for solvability is available based

on *matrix pencils*, see, for example, Brenan et al. (1996), and also reliable software for their analysis (Varga 2000).

Unfortunately, only certain classes of *nonlinear* DAEs can be *directly* solved numerically in a reliable way. For example, there are DAEs where no unique solution exists anymore when the step-size of the integrator approaches zero. For such systems step-size control is difficult, and numerical integration may easily fail. Domain-specific software, as, e.g., for mechanical systems, transforms the underlying DAE system into a form that can be more reliably solved using domain-specific knowledge. Hereby, certain equations of the DAE system are analytically differentiated, and special integration methods are used to solve the resulting overdetermined set of DAEs. In multi-domain simulation software, the following approaches are used:

- (a) The DAE system (1) is directly solved numerically using an implicit integration method, such as a linear multistep method. Typically, all VHDL-AMS simulators use this approach.
- (b) The DAE system (1) is symbolically transformed in a form that is equivalent to a set of ODEs, and then either explicit or implicit ODE or DAE integration methods are used to numerically solve the transformed system. The transformation is usually based on the algorithms of Pantelides (1988) and of Mattsson and Söderlind (1993) or some variants of them and might require to analytically differentiate equations. Typically, Modelica-based simulators, but also EcosimPro, use this approach.

For many models both approaches can be applied successfully. There are, however, systems where approach (a) is successful and fails for (b) or vice versa.

DAEs (1) derived from modeling languages usually have a large number of equations but with only a few unknowns in every equation. In order to solve DAEs of this kind efficiently, both with (a) or (b), typically graph theory and/or sparse matrix methods are utilized. For method (b) the

fundamental algorithms have been developed by Elmqvist (1978) and later improved in further publications. For a recent survey and comparison of some of the algorithms, see Frenkel et al. (2012).

Solving the DAE system (1) means to solve an initial value problem. In order that integration can be started, a consistent set of initial variables $\dot{\mathbf{x}}_0 = \dot{\mathbf{x}}(t_0)$, $\mathbf{x}_0 = \mathbf{x}(t_0)$, $\mathbf{w}_0 = \mathbf{w}(t_0)$, $\mathbf{y}_0 = \mathbf{y}(t_0)$, and $\mathbf{u}_0 = \mathbf{u}(t_0)$ has to be determined first at the initial time t_0 which is a nontrivial task. For example, often (1) shall start in steady state, that is, it is required that $\dot{\mathbf{x}}_0 := \mathbf{0}$ and therefore at the initial time (1) is required to satisfy

$$\mathbf{0} = \mathbf{f}(\mathbf{0}, \mathbf{x}_0, \mathbf{w}_0, \mathbf{y}_0, \mathbf{u}_0, t_0) \quad (2)$$

(2) is an algebraic system of nonlinear equations in the unknowns $\mathbf{x}_0$, $\mathbf{w}_0$, $\mathbf{y}_0$, and $\mathbf{u}_0$. These are $n_x + n_w + n_y$ equations for $n_x + n_w + n_y + n_u$ unknowns. Therefore, n_u further conditions must be provided (usually some elements of $\mathbf{u}_0$ and/or $\mathbf{y}_0$ are fixed to desired physical values). Solving (2) for the unknowns is also called “DC operating point calculation” or “trimming.” Nonlinear equation solvers are based on iterative methods that require usually a sufficiently accurate initial guess for all unknowns. In a large multi-domain system model, it is not practical that reasonable initial values must be provided for every DAE variable and therefore methods are needed to solve (2) even if generic guess values in a library are provided that might be far from the solution of the system at hand.

For analog electronic circuit simulations, a large body of theory, algorithms, and software is available to solve (2) based on homotopy methods. The basic idea is to solve a sequence of nonlinear algebraic equation systems by starting with an easy to solve simplified system, characterized by the homotopy parameter $\lambda = 0$. This system is continuously “deformed” until the desired one is reached at $\lambda = 1$. The solution at iteration i is used as guess value for iteration $i + 1$, and at every iteration, the solution is usually computed with a Newton–Raphson method. The simplest such approach is “source stepping”: the initial guess values of all electrical components

are set to “zero voltage” and/or “zero current.” All (voltage and current) sources start at zero, and their values are gradually increased until the desired source values are reached. This method may not converge, typically due to the severe nonlinearities at switching thresholds in logical circuits.

There are several, more involved approaches, called “probability-one homotopy” methods. For these method classes, proofs exist that they converge for all initial conditions globally with probability one (so practically always). These algorithms can only be applied for certain classes of DAEs; see, for example, the “variable stimulus probability-one homotopy” of Melville et al. (1993).

Although strong results exist for analog electrical circuit simulators, it is difficult to generalize them to the large class of multi-domain systems covered by a modeling language. In Modelica a “homotopy” operator was introduced into the language (Sielemann et al. 2011) in order that a library developer can formulate simple homotopy methods like the “source stepping” in a component library. A generalization of probability-one methods for multi-domain systems was developed in the dissertation of Sielemann (2012) and was successfully applied to air distribution systems described as one-dimensional thermo-fluid pipe flow.

Models for Control Systems

Models for Analysis

The multi-domain models from section “[Modeling Language Principles](#)” can be utilized to evaluate the properties of a control system by simulation. Also control systems can be designed by nonlinear optimization where at every optimization step one or several simulations of a plant model are executed. Furthermore, modeling environments usually provide pre- and/or post-processing methods to linearize the nonlinear DAE system (1) around a steady-state operating point or an operating point along the simulation trajectory

$$\begin{aligned} \mathbf{x}(t) &\approx \mathbf{x}_{op} + \Delta \mathbf{x}(t), & \mathbf{w}(t) &\approx \mathbf{w}_{op} + \Delta \mathbf{w}(t), \\ \mathbf{y}(t) &\approx \mathbf{y}_{op} + \Delta \mathbf{y}(t), & \mathbf{u}(t) &\approx \mathbf{u}_{op} + \Delta \mathbf{u}(t) \end{aligned} \quad (3)$$

resulting in

$$\begin{aligned} \Delta \dot{\mathbf{x}}_{\text{red}} &= \mathbf{A} \Delta \mathbf{x}_{\text{red}} + \mathbf{B} \Delta \mathbf{u} \\ \Delta \mathbf{y} &= \mathbf{C} \Delta \mathbf{x}_{\text{red}} + \mathbf{D} \Delta \mathbf{u} \end{aligned} \quad (4)$$

where $\mathbf{x}_{op}$, $\mathbf{w}_{op}$, $\mathbf{y}_{op}$, and $\mathbf{u}_{op}$ define the operating point, $\Delta \mathbf{x}_{\text{red}}$ is a vector consisting of elements of $\Delta \mathbf{x}$, vector $\Delta \mathbf{w}$ is eliminated by exploiting the algebraic constraints, and $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, and $\mathbf{D}$ are constant matrices. Simulation tools provide linear analysis and synthesis methods on this linearized system and/or export it for usage in an environment such as Julia, Maple, Mathematica®, MATLAB®, or Python®.

Multi-domain models might also be used directly in nonlinear Kalman filters, moving horizon estimators, or nonlinear model predictive control. For example, the company ABB is using moving horizon estimation and nonlinear model predictive control based on Modelica models in its product OPTIMAX® to significantly improve the start-up process of power plants (Franke and Doppelhamer 2006), for the control of virtual power plants and for other purposes.

Inverse Models

A large body of literature exists about the theory of nonlinear control systems that are based on *inverse* plant models; see, for example, (Isidori 1995). Methods such as feedback linearization, nonlinear dynamic inversion, or flat systems use an inverse plant model in the control loop. However, a major obstacle is how to *automatically* utilize an inverse plant model in a controller without being forced to manually set up the equations in the needed form which is not practical for larger systems. Modeling languages can solve this problem as discussed below.

Nonlinear inverse models can be utilized in various ways in a control system. The simplest approach, as feed forward controller, is shown in Fig. 6. Under the assumption that identical equations (1) are used for the plant and the inverse plant model (but the plant model has $\mathbf{u}$ as input and $\mathbf{y}$ as output, whereas the inverse plant

Multi-domain Modeling and Simulation, Fig. 6 Controller with inverse plant model in the feed forward path. The inverse plant model needs usually also derivatives of $\mathbf{y}_{\text{ref}}$ as inputs. These derivatives are provided by appropriate low-pass filters

model has $\mathbf{y}$ as input and $\mathbf{u}$ as output) and start at the same initial state, then from the construction, the control error $\mathbf{e}$ is zero and $\mathbf{y} = \mathbf{y}_{\text{ref},\text{filt}}$, so $\mathbf{y}$ is identical to the low-pass filtered reference signals. In other words, $\mathbf{y} \approx \mathbf{y}_{\text{ref}}$ for reference signals that have a frequency spectrum below the cutoff frequency of the low-pass filters. Since the assumption is actually not fulfilled, there will be a nonzero control error $\mathbf{e}$, and the feedback controller has to cope with it. This controller structure with a nonlinear inverse plant model has the advantage that the feed forward part is useful over the complete operating range of the plant.

Various other structures with nonlinear plant models are discussed in Looye et al. (2005), such as compensation controllers, feedback linearization controllers, and nonlinear disturbance observers. In Olsson et al. (2017), a Modelica extension is defined to directly construct (sampled data) feedback linearization controllers from (continuous-time) Modelica plant models. Furthermore, integration algorithms are proposed to solve nonlinear inverse models with hard real-time requirements.

It turns out that nonlinear inverse plant models can be generated automatically with the techniques that have been developed for modeling languages; see section “[Modeling Language Principles](#).” In particular, constructing an inverse model from (1) means that the inputs $\mathbf{u}$ are defined to be outputs, so they are no longer knowns but unknowns, and outputs $\mathbf{y}$ are defined to be inputs, so they are no longer unknowns but knowns. The resulting system is still a DAE

system and can therefore be handled as any other DAE system. Therefore, defining an inverse model with a modeling language just requires exchanging the definition of input and output signals. In Modelica, this can be graphically performed with the nonstandard input–output block from Fig. 7. This block has two inputs and two outputs and is described by the equations:

$$u1 = u2; \quad y1 = y2;$$

From a block diagram point of view, this looks strange. However, from a DAE point of view, this just states constraints between two input and two output signals. In Fig. 8, it is shown how this block can be used to invert a simple second-order system: the output of the low-pass filter is connected to the output of the second-order system (note, a direction connection of this kind violates the input–output block semantics, but an indirect connection via the InverseBlockConstraint block is possible) and therefore this model computes the input of the second-order system, from the input of the filter by inverting the second-order system.

A Modelica environment will generate from this type of definition the inverse model, thereby differentiating equations analytically and solving

algebraic variables of the model in a different way as for a simulation model. The whole transformation is nontrivial, but it is just the standard method used by Modelica tools as for any other type of DAE system.

The question arises whether a solution of the inverse model exists or is unique and whether the model is stable (otherwise, it cannot be applied in a control system). In general, a nonlinear inverse model consists of linear and/or nonlinear algebraic equation systems and of linear and/or nonlinear differential equations. Therefore, from a formal point of view, the same theorems as for a general DAE system applies, see Brenan et al. (1996). Furthermore, all these equations need to be solved with a numerical method. For some classes of systems, it can be shown that a unique mathematical solution exists and that the system is stable. However, in general, one cannot expect that it is possible to provide such a proof for complex inverse plant models. In some cases it is possible to approximate the plant model so that its inverse is guaranteed to be stable. In more involved cases, it might only be possible to perform simulations at many operating points to show that the probability of a stable inverse model is high. Note, nonlinear inverse plant models have been successfully utilized by automatic generation from a Modelica plant model, in particular for robots, satellites, aircrafts, vehicles, and thermo-fluid systems.

Multi-domain Modeling and Simulation,
Fig. 7 Modelica InverseBlockConstraint block

The Functional Mockup Interface

Many different types of simulation environments are in use. One cannot expect that a generic approach as sketched in section “Modeling

Multi-domain Modeling and Simulation,
Fig. 8 Inversion of a second-order system in Modelica

Language Principles” will replace all these environments with their rich set of domain-specific knowledge, analysis, and synthesis features. Practically, all simulation environments provide a vendor-specific interface in order that a user can import components that are not describable by the simulation environment itself. Typically, this requires to provide a component as a set of C or Fortran functions with a particular calling interface. In the control community, the most widely used approach of this kind is the S-Function interface from the MathWorks, where Simulink is used as integration platform, and model components from other environments are imported as S-Functions.

In 2010 the vendor-independent standard “Functional Mockup Interface 1.0” was developed, followed by a significantly improved version 2.0 in 2014 (Modelica Association 2014). An again significantly improved version 3.0 is under development as of June 2019 (see <https://fmi-standard.org/faq/>). FMI is a low-level standard for the exchange of models between different simulation environments. This standard allows to exchange only the model equations (called “FMI for Model Exchange”) and/or the model equations with an embedded solver (called “FMI for Co-Simulation”). This standard was quickly adopted by many simulation environments, and in 2019 there are more than 130 tools that support it (for an actual list of tools, see <https://fmi-standard.org/tools/>). In particular Modelica environments export Modelica models in this format, and therefore, Modelica multi-domain models can be imported in other environments with low effort.

A software component which implements the FMI is called Functional Mockup Unit (FMU). An FMU consists of one zip file with extension “.fmu” containing all necessary components to utilize the FMU either for Model Exchange, for Co-Simulation, or for both. The following summary is an adapted version from Blochwitz et al. (2012):

1. An *XML-file* contains the definition of all exposed variables of the FMU, as well as other model information. It is then possible to

run the FMU on a target system without this information, that is, without unnecessary overhead. Furthermore, this allows determining all properties of an FMU from a text file, without actually loading and running the FMU.

2. A set of *C-functions* is provided to execute model equations for the Model Exchange case and to simulate the equations for the Co-Simulation case. These C-functions can be provided either in binary form for different platforms or in source code. The different forms can be included in the same model zip file.
3. Further data can be included in the FMU zip file, especially a model icon (bitmap file), documentation files, maps and tables needed by the model, and/or all object libraries or DLLs that are utilized.

The main application area of FMI is offline simulation, but it is also used for (soft) real-time applications, see, for example, the direct support of FMI in the real-time systems of dSPACE (<https://www.dspace.com>). In Brembeck (2019) a nonlinear (continuous-time) Modelica model of a highly maneuverable electric vehicle is used as starting point of a dedicated tool chain to generate automatically (sampled data) FMUs used as discrete-time prediction models for an extended moving horizon state estimator and an extended Kalman filter.

Summary and Future Directions

Multi-domain modeling based on a DAE description and defined with a modeling language is an established approach, and many tools support it. This allows to conveniently define plant models from many domains for the design and evaluation of control systems. Furthermore, nonlinear inverse plant models can be easily constructed with the same methodology and can be utilized in various ways in nonlinear control systems.

Current research focuses on the support of the complete life cycle: defining requirements of a system formally on a “high level,” considerably improving testing by checking these

requirements automatically when evaluating a system design by simulations, see, for example, Bouskela and Jardin (2018), and providing complete tool chains to embedded systems. For example, in the European ITEA project EMPHYSIS (embedded systems with physical models in the production code software; <https://itea3.org/project/emphysis.html>), the variant eFMI of FMI is being developed in the years 2017–2021 so that whole tool chains from multi-domain modeling environments to production code on automotive electronic control units and other embedded devices with *hard real-time requirements* become feasible. This will allow convenient and fast target code generation of nonlinear controllers, optimization-based controllers, extended and unscented Kalman filters, or moving horizon estimators from multi-domain models.

Furthermore, the methodology itself is further improved. Especially, with the prototyping platform Modia (Elmqvist et al. 2017), new directions are evaluated, such as hybrid 2D schematic/3D graphical user interfaces, close integration of complex data structures with equation-based modeling (e.g., to model multiphase, multicomponent fluids or collision handling of 3D mechanical systems), improved and new symbolic transformation algorithms (Otter and Elmqvist 2017), code generation for large models, support of multi-domain Dirac impulses, and changing the number of equations during simulation.

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs

Xiang Chen¹ and Kemin Zhou²

¹Department of Electrical and Computer Engineering, University of Windsor, Windsor, ON, Canada

²School of Electrical and Automation Engineering, Shangdong University of Science and Technology, Shangdong, China

Abstract

In this entry, the implementation of Youla-Kučera parameterization of all stabilizing controllers for feedback control systems is first presented. Robust and optimal control designs are then discussed within the multi-objective design framework. In particular, $\mathcal{H}_\infty$ Gaussian control design and a linear-quadratic-Gaussian (LQG) control with an extra $\tilde{Q}$ -regulation design are showcased and compared. The pros and cons of the two different multi-objective optimal control approaches are compared and the potential further research activities are discussed for the multi-objective control design.

Keywords

Youla-Kučera parameterization · Multi-objective control · $\mathcal{H}_\infty$ Gaussian control · LQG control · $\tilde{Q}$ -regulation

Introduction

Multi-objective optimal designs play significant roles in control system theory due to the fact that multi-performances are always of concerns in

practical systems. The traditional multi-objective optimal control is normally conducted in one integrated controller framework, that is, a single controller structure is developed to address all performance expectations simultaneously. However, the stringent reality facing various expectations is that they might be inherently conflicting to each other, such as the well-known conflicting pair of robustness and optimality in a robust control system. Therefore, in the case of one controller design, the best strategy would be (and has to be) to achieve a trade-off between conflicting performance requirements, which would then incur the fundamental drawback for such kind of control designs, the conservativeness. An ideal remedy of this drawback would call for “complementary control” design framework instead of conventional “trade-off control,” where no significant progress has been observed so far. The main contents of this entry, thus, is to demonstrate and compare the ideas of “one- and two-feedback controller” designs through showcasing the $\mathcal{H}_\infty$ Gaussian control (Chen and Zhou 2001) and an LQG control with extra $\tilde{Q}$ -regulation design proposed most recently in Chen et al. (2019), which is essentially motivated by the equivalent “multi-block” implementation of Youla-Kučera parameterization of all stabilizing controllers (Zhou and Ren 2001; Kučera 1979; Youla et al. 1976a). While both designs are essentially for $\mathcal{H}_2/\mathcal{H}_\infty$ performance, the later apparently facilitates a new multi-objective optimal design framework. The pros and cons of these two different designs are then compared, and the further research activities are suggested for the new multi-objective control design framework.

This entry is divided into five sections. After the Introduction, the Youla-Kučera parameterization of all stabilizing controllers is presented for a feedback system. Section “ $\mathcal{H}_\infty$ Gaussian Control” will be devoted to the $\mathcal{H}_\infty$ Gaussian control design, while, in section “ LQG Control with $\tilde{Q}$ -Regulation”, the multi-objective optimal design is demonstrated by a newly developed LQG control with extra $\tilde{Q}$ -regulation design. The entry is then concluded in section “Summary and Future Directions” with some discussions

for the two design approaches and for the future research activities.

The symbols used are standard. I is an identity matrix with the consistent dimension in contexts. $\delta(t)$ is an impulse function. The transpose of a matrix A is represented by A^T , and the determinant of a square matrix A is denoted as $\det(A)$. $G(s) = \begin{bmatrix} A & B \\ C & D \end{bmatrix} = D + C(sI - A)^{-1}B$ with (A, B, C, D) being a realization of $G(s)$ in the state space. $\mathcal{RH}_\infty$ is the space of all proper and real rational stable transfer function matrices with the norm $\|T(s)\|_\infty = \sup_{\omega} \bar{\sigma}\{T(j\omega)\}$ for any $T(s) \in \mathcal{RH}_\infty$, where $\bar{\sigma}\{\cdot\}$ is the largest singular value of the underlying matrix $\rho(X) = \max_i |\lambda_i(X)|$ is the spectral radius of a matrix X (Zhou et al. 1996), where $\lambda_i(X)$, $i = 1, 2, \dots, n$ are the eigenvalues of X .

Youla-Kučera Parameterization and Implementation

We start with the definition of the coprime factorization over $\mathcal{RH}_\infty$ of a transfer function matrix $P(s)$.

Definition 1 (Zhou et al. 1996) Given a proper real rational transfer function matrix $P(s)$, a right coprime factorization of $P(s)$ over $\mathcal{RH}_\infty$ is defined as $P(s) = N(s)M^{-1}(s)$, where $N(s), M(s) \in \mathcal{RH}_\infty$ and satisfy the Bezout identity:

$$\begin{bmatrix} X_r(s) & Y_r(s) \end{bmatrix} \begin{bmatrix} M(s) \\ N(s) \end{bmatrix} = I, \quad \text{or} \\ X_r(s)M(s) + Y_r(s)N(s) = I,$$

for some $X_r(s), Y_r(s) \in \mathcal{RH}_\infty$.

Correspondingly, a left coprime factorization of $P(s)$ over $\mathcal{RH}_\infty$ is defined as $P(s) = \tilde{M}^{-1}(s)\tilde{N}(s)$, where $\tilde{N}(s), \tilde{M}(s) \in \mathcal{RH}_\infty$ and satisfy the Bezout identity:

$$\begin{bmatrix} \tilde{M}(s) & \tilde{N}(s) \end{bmatrix} \begin{bmatrix} X_l(s) \\ Y_l(s) \end{bmatrix} = I, \quad \text{or}$$

$$\tilde{M}(s)X_I(s) + \tilde{N}(s)Y_I(s) = I,$$

for some $X_I(s), Y_I(s) \in \mathcal{RH}_\infty$.

A linear time-invariant (LTI) feedback control system is shown in Fig. 1, where $G(s) = \begin{bmatrix} A & B \\ C & D \end{bmatrix} = D + C(sI - A)^{-1}B$ is a nominal plant model and $C(s)$ is a controller designed such that the closed-loop system is stable.

Let $C(s) = \tilde{V}^{-1}(s)\tilde{U}(s)$ and $G(s) = \tilde{M}^{-1}(s)\tilde{N}(s)$ be the (left) coprime factorizations of $C(s)$ and $G(s)$. The Youla-Kučera parameterization of all stabilizing controllers for $G(s)$ can then be expressed as

$$K(s) = (\tilde{V}(s) - Q(s)\tilde{N}(s))^{-1}(\tilde{U}(s) + Q(s)\tilde{M}(s)),$$

where $Q(s) \in \mathcal{RH}_\infty$ and $\det(\tilde{V}(\infty) - Q(\infty)\tilde{N}(\infty)) \neq 0$ and, apparently, $C(s)$ is a special case of $K(s)$ when $Q(s) = 0$. Note that, equivalently, $K(s)$ can be implemented in a conventional “single-block” controller structure shown in Fig. 2 or, as proposed in Zhou and Ren (2001), in a “multi-block” controller structure featuring a residual signal-driven Q -Regulation, as shown in Fig. 3.

While $Q(s)$ can be arbitrarily chosen in $\mathcal{RH}_\infty$ and independent on $C(s)$, one can see that $Q(s)$ is actually integrated with $C(s)$ to form a single-controller $K(s)$ in Fig. 2, but $Q(s)$ in Fig. 3 essentially brings in another freedom of design

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 1 A feedback control system

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 2 Conventional “single-block” controller structure

other than $C(s)$ as it is driven by an explicit residue signal $f = \tilde{N}(s)u - \tilde{M}(s)y$ and generates an extra regulating signal u_f . This residual signal f can be calculated as exactly the difference between the sensor output of the real plant and the estimated sensor output of a standard Luenberger observer of the plant, hence, providing a reasonable measure of the modeling error in practice (Chen et al. 2019; Zhou and Ren 2001).

It is easy to see that, with the Youla-Kučera parameterization of all stabilizing controllers, any multi-objective optimal controller for specified performances, if existing, should correspond to an appropriately selected $Q(s)$ since the optimal controller must first be a stabilizing controller. Therefore, the “single-block” and “multi-block” implementations actually point to the different frameworks of multi-objective optimal control designs.

$\mathcal{H}_\infty$ Gaussian Control

It is clear that a multi-objective optimal control design can be conducted within the “centralized” structure depicted in Fig. 2. However, even if Youla-Kučera structure provides excellent insights of the design of optimal controllers, it, unfortunately, does not offer easy solutions in transfer functions to various optimization problems. Practically, instead of directly searching for an optimal $Q(s)$, the design of optimal controllers can be alternatively done in the state space with the same “centralized” controller structure. For example, a popular multi-objective optimal control problem known as the “mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control” (Bernstein and Haddad 1989; Chen and Zhou 2001; Khargonekar and Rotea 1991; Zhou et al. 1994) can be formulated in Fig. 4, or, equivalently, in Fig. 5 as represented in the linear fractional transformation (LFT) format, where (A_c, B_c, C_c, D_c) is the controller realization in

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ **Control Designs,****Fig. 3** “Multi-block”
controller structure
featuring Q -regulation**Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$** **Control Designs, Fig. 4**Mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control
design in state space

the state space, w represents the modeling uncertainty disturbance, and w_0 is a (vector) white noise. It is well-known that $\mathcal{H}_\infty$ and $\mathcal{H}_2$ performances of a control system are normally applied to address the impacts of w and w_0 , respectively, characterized as the robust and optimal performances of the control system. In the remaining part of this section, the “ $\mathcal{H}_\infty$ Gaussian Control” design (Chen and Zhou 2001) is presented as a sample study, which is essentially a mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control design utilizing the “centralized” implementation of Youla-Kučera parameterization.

Let us introduce first the set of all bounded power signals and the power norm defined in this set: Given a real vector stochastic signal $u(t)$:

$$u(t) = [u_1(t) \ u_2(t) \ \cdots \ u_m(t)]^T \in \mathbb{R}^m, \quad \forall t \in \mathbb{R},$$

where $u_i(t)$, $i = 1, \dots, m$ are real stationary random processes, define the **mean** and averaged **auto-correlation matrices** of $u(t)$, respectively, as follows:

$$E\{u\} := [E\{u_1(t)\} \ E\{u_2(t)\} \ \cdots \ E\{u_m(t)\}]^T,$$

$$R_{uu}(\tau) := \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T E\{u(t+\tau)u^T(t)\}dt.$$

**Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 5**Mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control design in LFT expression

The Fourier transform of $R_{uu}(\tau)$, if exists, is $S_{uu} := \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{uu}(\tau)e^{-j\omega\tau}d\tau$. The so-called bounded power signal is defined as follows:

Definition 2 A vector stationary stochastic signal u is said to have bounded power if

1. both R_{uu} and S_{uu} exist;
2. $\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T E\|u(t)\|^2 dt < \infty$.

Let $\mathcal{P}$ be the space of all signals with bounded power. A semi-norm can be defined on $\mathcal{P}$

$$\|u\|_{\mathcal{P}} := \sqrt{\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T E\{\|u(t)\|^2\}dt} \\ = \sqrt{\text{trace}[R_{uu}(0)]}, \quad \forall u \in \mathcal{P}.$$

In this entry, the well-known Gaussian white noise $w_0(t)$ is taken as a zero-mean stationary process with an identity power spectrum, that is, $E\{w_0(t)\} \equiv 0$ and $E\{w_0(t)w_0^T(\tau)\} = I\delta(t - \tau)$. Independence between stochastic signals is defined below.

Definition 3 Two vector stationary stochastic signals $w_1(t)$ and $w_2(t)$ are said to be independent if, for any $t_1 \geq 0$ and $t_2 \geq 0$, we have

$$E\{w_1(t_1)w_2^T(t_2)\} = E\{w_1(t_1)\}E\{w_2^T(t_2)\}.$$

Now consider an LTI system described by

$$\dot{x} = Ax + B_0w_0 + B_1w + B_2u, \quad x(0) = 0, \quad (1)$$

$$z = C_1x + D_{12}u, \quad R_1 := D_{12}^T D_{12} > 0, \quad (2)$$

$$y = C_2x + D_{20}w_0, \quad R_0 := D_{20}D_{20}^T > 0, \quad (3)$$

where w is a bounded power signal, w_0 is a white noise signal, w and w_0 are independent. The $\mathcal{H}_\infty$ Gaussian control can be formulated as in Fig. 6 with the control law taking the observer-based form, consisting of a state feedback gain F and an observer gain L :

$$\dot{\hat{x}} = \hat{A}\hat{x} + B_2u - Ly, \quad \hat{x}(0) = 0, \quad (4)$$

$$u = F\hat{x}. \quad (5)$$

Let $e_x := x - \hat{x}$ and define the following performance indices with a given $\gamma > 0$:

$$J_1(u, w, w_0) := \gamma^2 \|w\|_{\mathcal{D}}^2 - \|z\|_{\mathcal{D}}^2,$$

$$J_2(u, w, w_0) := \|e_x\|_{\mathcal{D}}^2.$$

Then the $\mathcal{H}_\infty$ Gaussian control design is to: find a feedback control law u_* in the given form (4)–(5) such that

$$J_1(u_*, w_*, w_0) \leq J_1(u_*, w, w_0), \quad \forall w \in \mathcal{P}_s;$$

$$J_2(u_*, w_*, w_0) \leq J_2(u, w_*, w_0),$$

where w_* is called the worst disturbance signal.

A theorem is stated for this $\mathcal{H}_\infty$ Gaussian control problem and concludes this section. To simplify the notations, the following abbreviations are introduced:

$$A_x := A - B_2R_1^{-1}D_{12}^T C_1,$$

$$A_y := A - B_0D_{20}^T R_0^{-1} C_2,$$

$$P := B_0(I - D_{20}^T R_0^{-1} D_{20})B_0^T,$$

$$Q := C_1^T(I - D_{12}R_1^{-1}D_{12}^T)C_1.$$

Theorem 1 Let the dynamical system G described by Eqs. (1), (2), and (3) satisfy the following assumptions:

(A1) (A, B_2) is stabilizable and (C_2, A) is detectable.

(A2) $\begin{bmatrix} A - j\omega I & B_2 \\ C_1 & D_{12} \end{bmatrix}$ has full column rank for all ω .

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 6

$\mathcal{H}_\infty$ Gaussian control design

(A3) $\begin{bmatrix} A - j\omega I & B_0 \\ C_2 & D_{20} \end{bmatrix}$ has full row rank for all ω .

If there are stabilizing solutions $P_1 \geq 0$, $P_2 \geq 0$ and $P_3 \geq 0$ solving the following Riccati equations:

$$\begin{aligned} A_x^T P_1 + P_1 A_x + P_1 (B_1 B_1^T / \gamma^2 - B_2 R_1^{-1} B_2^T) P_1 + Q &= 0, \\ P_2 (A_y + \gamma^{-2} B_1 B_1^T P_1 - P_3 C_2^T R_0^{-1} C_2) + (A_y + \gamma^{-2} B_1 B_1^T P_1 - P_3 C_2^T R_0^{-1} C_2)^T P_2 \\ + \gamma^{-2} P_2 B_1 B_1^T P_2 + (D_{12}^T C_1 + B_2^T P_1)^T R_1^{-1} (D_{12}^T C_1 + B_2^T P_1) &= 0, \\ [A_y + \gamma^{-2} B_1 B_1^T (P_1 + P_2)] P_3 + P_3 [A_y + \gamma^{-2} B_1 B_1^T (P_1 + P_2)]^T - P_3 C_2^T R_0^{-1} C_2 P_3 + P &= 0, \end{aligned}$$

i.e., $A_x + (B_1 B_1^T / \gamma^2 - B_2 R_1^{-1} B_2^T) P_1$, and $A_y + \gamma^{-2} B_1 B_1^T (P_1 + P_2) - P_3 C_2^T R_0^{-1} C_2$ are both stable, then there exist the optimal control law u_* and the worst disturbance signal w_* such that:

$$J_1(u_*, w_*, w_0) \leq J_1(u_*, w, w_0),$$

$$J_2(u_*, w_*, w_0) \leq J_2(u, w_*, w_0).$$

If the solutions exist, then $w_* = \gamma^{-2} B_1^T (P_1 x + P_2 e)$ and the optimal controller is given by:

$$\dot{\hat{x}} = \hat{A} \hat{x} + B_2 u_* - L_* y,$$

$$u_* = F_* \hat{x}, \quad \hat{x}(0) = 0,$$

where $\hat{A} = A + \gamma^{-2} B_1 B_1^T P_1 + L_* C_2$, $F_* = -R_1^{-1} (D_{12}^T C_1 + B_2^T P_1)$, and $L_* = -(B_0 D_{20}^T + P_3 C_2^T) R_0^{-1}$.

Conversely, let $P_1 \geq 0$ be a stabilizing solution to

$$\begin{aligned} A_x^T P_1 + P_1 A_x + P_1 (B_1 B_1^T / \gamma^2 \\ - B_2 R_1^{-1} B_2^T) P_1 + Q &= 0. \end{aligned}$$

Suppose there exist a w'_* and a controller u_* (hence, a L_*)

$$\begin{aligned} \dot{\hat{x}} &= (A + \gamma^{-2} B_1 B_1^T P_1 + L_* C_2 + B_2 F_*) \hat{x} \\ &\quad - L_* y, \end{aligned}$$

$$u_* = F_* \hat{x}, \quad F_* = -R_1^{-1} (D_{12}^T C_1 + B_2^T P_1),$$

achieving $0 < J_1(u_*, w'_*, 0) \leq J_1(u_*, w, 0)$. Then there exists a w_* achieving $J_1(u_*, w_*, w_0) \leq J_1(u_*, w, w_0)$. If, furthermore, this w_* also achieves $J_2(u_*, w_*, w_0) \leq J_2(u, w_*, w_0)$, then there exist $P_2 \geq 0$ and $P_3 \geq 0$ solving:

$$\begin{aligned} P_2 (A_y + \gamma^{-2} B_1 B_1^T P_1 - P_3 C_2^T R_0^{-1} C_2) + (A_y + \gamma^{-2} B_1 B_1^T P_1 - P_3 C_2^T R_0^{-1} C_2)^T P_2 \\ + \gamma^{-2} P_2 B_1 B_1^T P_2 + (D_{12}^T C_1 + B_2^T P_1)^T R_1^{-1} (D_{12}^T C_1 + B_2^T P_1) &= 0, \\ [A_y + \gamma^{-2} B_1 B_1^T (P_1 + P_2)] P_3 + P_3 [A_y + \gamma^{-2} B_1 B_1^T (P_1 + P_2)]^T - P_3 C_2^T R_0^{-1} C_2 P_3 + P &= 0. \end{aligned}$$

Moreover, if $A + \gamma^{-2} B_1 B_1^T (P_1 + P_2) - (B_0 D_{20}^T + P_3 C_2^T) R_0^{-1} C_2$ is stable, then $L_* = -(B_0 D_{20}^T + P_3 C_2^T) R_0^{-1}$.

The trade-off performance can be clearly observed as the controller becomes an LQG control (hence, an $\mathcal{H}_2$ control too) exactly when $\gamma \rightarrow \infty$, and, if there is no white noise posed in the model, the controller returns back to the

$\mathcal{H}_\infty$ design. Otherwise, the controller delivers performance that is in between $\mathcal{H}_\infty$ and $\mathcal{H}_2$, hence, a mixed one.

LQG Control with $\tilde{Q}$ -Regulation

It is not difficult to figure out the following two facts related to the “multi-block” with

Q -regulation implementation of the Youla-Kučera parameterization in Fig. 3:

- Figure 3 can be converted into the configuration in Fig. 7:

where $Q(s) = \tilde{V}(s)\tilde{Q}(s) \in \mathcal{RH}_\infty$ is an admissible Youla-Kučera parameter in Fig. 3 if $\tilde{Q}(s)$ in Fig. 7 is designed to be a proper stable transfer function matrix.

- The structure posed by $\tilde{N}(s)$ and $\tilde{M}(s)$ in Figs. 3 and 7 actually mimics exactly a standard Luenberger observer (Chen et al. 2019; Zhou and Ren 2001) and $f = \tilde{N}u - \tilde{M}y = \hat{y} - y$, $\hat{y} = C_2\hat{x}$, as shown in Fig. 8

These two insights immediately motivate us to consider the new controller structure in Fig. 9 for the multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ control problem originally posed in Fig. 4

As pointed out in Zhou and Ren (2001), the controller (A_c, B_c, C_c, D_c) and the $\tilde{Q}$ -regulation

can be designed independently. Considering that $\tilde{Q}$ is driven by the residual signal $f = \hat{y} - y$, the structure in Fig. 9 brings in the hope that the conservativeness rooted in the “single-block” controller design could be meaningfully reduced, if not completely removed. $C(s)$ with extra $\tilde{Q}$ -regulation design, hence, can be deemed as a new mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control design although it still originates from the Youla-Kučera parameterization. Furthermore, it is noted that, in Fig. 9 the LQG controller is in Luenberger observer-based structure, characterized by an observer gain L and a state feedback gain F , and driven by the same sensor output y . Therefore it is then reasonable to take the advantage of the controller structure with the shared observer as shown in Fig. 10

In this section, a sample study originated from (Chen et al. 2019) is presented, by taking (A_c, B_c, C_c, D_c) as an LQG controller and designing $\tilde{Q}$ -regulation in the $\mathcal{H}_\infty$ sense.

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 7
Converted “multi-block” controller structure with $\tilde{Q}$ -regulation

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 8
State-space interpretation of $\tilde{N}(s)$ and $\tilde{M}(s)$

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 9
Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ control in “multi-block” design

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 10

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ control with shared observer

The following model is a slightly extended with case of that in (1), (2), and (3) with the same interpretation of signals:

$$\dot{x} = Ax + B_1w + B_0w_0 + B_2u, \quad (6)$$

$$z = C_1x + D_{12}u, \quad (7)$$

$$y = C_2x + D_{21}w + D_{20}w_0, \quad (8)$$

Extra (but standard) assumptions are made for the system in (6), (7), and (8) (Doyle et al. 1989), other than the Assumptions (A1)–(A3):

(A4) (A, B_1) is stabilizable and (C_1, A) is detectable.

(A5) $\begin{bmatrix} A - j\omega I & B_1 \\ C_2 & D_{21} \end{bmatrix}$ has full row rank for all ω .

(A6) $R_1 = D_{12}^T D_{12} > 0$, $R_2 = D_{21} D_{21}^T > 0$, and $R_0 = D_{20} D_{20}^T > 0$.

Let F and L be the state feedback, and the observer gains designed for an LQG control of the nominal system ($w = 0$) in (6), (7), and (8), that is, $F = -R_1^{-1}(D_{12}^T C_1 + B_2^T P_{10})$, $L = -(B_0 D_{20}^T + P_{20} C_2^T) R_0^{-1}$, where $P_{10} \geq 0$ and $P_{20} \geq 0$ solve

$$P_{10}A_{10} + A_{10}^T P_{10} - P_{10}B_2R_1^{-1}B_2^T P_{10} + Q_{10} = 0, \quad (9)$$

$$P_{20}A_{20}^T + A_{20}P_{20} - P_{20}C_2^T R_0^{-1}C_2 P_{20} + Q_0 = 0, \quad (10)$$

$$A_{10} = A - B_2R_1^{-1}D_{12}^T C_1,$$

$$A_{20} = A - B_0D_{20}^T R_0^{-1}C_2,$$

$$Q_{10} = C_1^T (I - D_{12}R_1^{-1}D_{12}^T)C_1,$$

$$Q_0 = B_0(I - D_{20}^T R_0^{-1}D_{20})B_0^T.$$

Apparently, the system with the implemented LQG controller carries the model as:

$$\dot{x} = Ax + B_1w + B_2u_l + B_2u_f, \quad (11)$$

$$\dot{\hat{x}} = (A + LC_2)\hat{x} + B_2u_l + B_2u_f - Ly, \quad (12)$$

$$z = C_1x + D_{12}u_l + D_{12}u_f, \quad (13)$$

$$y = C_2x + D_{21}w, \quad (14)$$

$$u_l = F\hat{x}, \quad u_f = \tilde{Q}(f), \quad f = C_2\hat{x} - y. \quad (15)$$

Since the LQG control is not designed to address the uncertainty disturbance w , the additional regulating signal $u_f = \tilde{Q}(f)$, hence, should be designed to bring back the robust performance which naturally falls into the category of $\mathcal{H}_\infty$ control. Therefore, the problem addressed in this section can be formulated as follows:

For the augmented system (11), (12), (13), (14), and (15) under the LQG control u_l characterized with F and L , as shown in Fig. 10, we need to find a regulating controller $\tilde{Q}$ such that $u_f = \tilde{Q}(f)$ achieves $\|T_{zw}(s)\|_\infty < \gamma$, where γ is a prescribed value, and $T_{zw}(s)$ is the closed-loop transfer function from w to z .

Note that the system model (11), (12), (13), (14), and (15) can be equivalently converted into the following augmented format, after implementing F and L and introducing $e = x - \hat{x}$ as the estimation error variable for the LQG control:

$$\begin{aligned}\dot{\hat{x}} &= (A + B_2 F)x - B_2 F e + B_1 w + B_2 u_f, \\ \dot{e} &= (A + LC_2)e + (B_1 + LD_{21})w, \\ z &= (C_1 + D_{12}F)x - D_{12}Fe + D_{12}u_f, \\ f &= -C_2 e - D_{21}w, \\ u_f &= \tilde{Q}(f).\end{aligned}$$

Define:

$$\bar{x} = \begin{bmatrix} x \\ e \end{bmatrix}, \quad \bar{A} = \begin{bmatrix} A + B_2 F & -B_2 F \\ 0 & A + LC_2 \end{bmatrix},$$

$$\bar{D}_{12} = D_{12},$$

$$\bar{B}_1 = \begin{bmatrix} B_1 \\ B_1 + LD_{21} \end{bmatrix}, \quad \bar{B}_2 = \begin{bmatrix} B_2 \\ 0 \end{bmatrix},$$

$$\bar{D}_{21} = -D_{21},$$

$$\bar{C}_1 = [C_1 + D_{12}F - D_{12}F], \quad \bar{C}_2 = [0 - C_2].$$

Then the model can be finally rewritten as:

$$\dot{\bar{x}} = \bar{A}\bar{x} + \bar{B}_1 w + \bar{B}_2 u_f, \quad (16)$$

$$z = \bar{C}_1 \bar{x} + D_{12} u_f, \quad (17)$$

$$f = \bar{C}_2 \bar{x} + \bar{D}_{21} w, \quad (18)$$

$$u_f = \tilde{Q}(f). \quad (19)$$

This control problem can be, again, expressed in the LFT format, as shown in Fig. 11.

Now we can present the following Theorem (Chen et al. 2019):

Theorem 2 For the system in (16), (17), (18), and (19) as shown in Fig. 11, given a $\gamma > 0$, there exists an admissible regulating controller $\tilde{Q}$ such that $\|T_{zw}(s)\|_\infty < \gamma$ if and only if the following conditions are satisfied:

1. There exist $P_1 \geq 0$ and $P_2 \geq 0$ solve the following two Riccati equations:

Multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ Control Designs, Fig. 11
Control of augmented system

$$\begin{aligned}P_1 A_{10} + A_{10}^T P_1 \\ + P_1 \left(\frac{B_1 B_1^T}{\gamma^2} - B_2 R_1^{-1} B_2^T \right) P_1 + Q_{10} = 0, \quad (20)\end{aligned}$$

$$\begin{aligned}P_2 A_2^T + A_2 P_2 \\ + P_2 \left(\frac{C_1^T C_1}{\gamma^2} - C_2^T R_2^{-1} C_2 \right) P_2 + Q_2 = 0, \quad (21)\end{aligned}$$

where

$$A_2 = A - B_1 D_{21}^T R_2^{-1} C_2,$$

$$Q_2 = B_1 (I - D_{21}^T R_2^{-1} D_{21}) B_1^T.$$

2. $\rho(P_1 P_2) < \gamma^2$.

Moreover, one such admissible controller, if exists, can be obtained as:

$$\dot{x}_q = A_q x_q + B_q f,$$

$$u_f = F_* x_q,$$

where

$$\begin{aligned}A_q &= \bar{A} + \gamma^{-2} \bar{B}_1 \bar{B}_1^T \bar{P}_1 + \bar{B}_2 F_* \\ &\quad - B_q (\bar{C}_2 - \gamma^{-2} D_{21} \bar{B}_1^T \bar{P}_1),\end{aligned}$$

$$B_q = -(I - \gamma^{-2} \bar{P}_2 \bar{P}_1)^{-1} L_*,$$

$$\bar{P}_1 = \begin{bmatrix} P_1 & 0 \\ 0 & 0 \end{bmatrix}, \quad \bar{P}_2 = \begin{bmatrix} P_2 & P_2 \\ P_2 & P_2 \end{bmatrix},$$

$$F_* = -[F + R_1^{-1} (B_2^T P_1 + D_{12}^T C_1) - F],$$

$$L_* = \begin{bmatrix} (P_2 C_2^T + B_1 D_{21}^T) R_2^{-1} \\ (P_2 C_2^T + B_1 D_{21}^T) R_2^{-1} + L \end{bmatrix}.$$

Remark 1 Based on Theorem 2, the new multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ control design procedures can be summarized as follows:

1. Solving P_{10} and P_{20} from (9) and (10) and finding $F = -R_1^{-1}(D_{12}^T C_1 + B_2^T P_{10})$, $L = -(B_0 D_{20}^T + P_{20} C_2^T) R_0^{-1}$, this is the LQG control design.
2. Solving P_1 and P_2 from (20) and (21) and finding $F_* = -[F + R_1^{-1}(B_2^T P_1 + D_{12}^T C_1) - F]$, $L_* = \begin{bmatrix} (P_2 C_2^T + B_1 D_{21}^T) R_2^{-1} \\ (P_2 C_2^T + B_1 D_{21}^T) R_2^{-1} + L \end{bmatrix}$, this is the $\mathcal{H}_\infty$ control design.
3. The multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ controller can be constructed as:

$$\begin{aligned}\dot{x}_q &= A_q x_q + B_q f, \\ u_f &= F_* x_q,\end{aligned}$$

where

$$\begin{aligned}A_q &= \bar{A} + \gamma^{-2} \bar{B}_1 \bar{B}_1^T \bar{P}_1 + \bar{B}_2 F_* \\ &\quad - B_q (\bar{C}_2 - \gamma^{-2} D_{21} \bar{B}_1^T \bar{P}_1), \\ B_q &= -(I - \gamma^{-2} \bar{P}_2 \bar{P}_1)^{-1} L_*, \\ \bar{P}_1 &= \begin{bmatrix} P_1 & 0 \\ 0 & 0 \end{bmatrix}, \quad \bar{P}_2 = \begin{bmatrix} P_2 & P_2 \\ P_2 & P_2 \end{bmatrix}.\end{aligned}$$

Summary and Future Directions

While both the mixed $\mathcal{H}_2/\mathcal{H}_\infty$ design with single controller and the LQG control with extra $\tilde{Q}$ -regulation address multi-objective performance in $\mathcal{H}_2$ and $\mathcal{H}_\infty$ senses, the fundamental difference between these two approaches lies in the fact that the design goal of the former is to achieve the (best) trade-off of conflicting performances, while that of the latter is to provide appropriate complements within conflicting performance by taking the advantage of the extra (and independent) regulating control signal. Although the traditional multi-objective $\mathcal{H}_2/\mathcal{H}_\infty$ design may

enjoy the benefit of low controller order, it is, however, at the expense of conservative control performance. For example, in the $\mathcal{H}_\infty$ Gaussian control design, γ actually can be used as the tuning parameter as the weight between the robustness and the optimality, noting the fact that, by taking $\gamma \rightarrow \infty$, the solution will be reduced to the LQG control, hence, achieving the optimal performance but the least robustness. On the other hand, the lower the γ value, the closer the solution to the $\mathcal{H}_\infty$ control, meaning a better robustness but more compromised optimal performance. In the case of the LQG with $\tilde{Q}$ -regulation design, it is obvious that the design of LQG control is independent of the design of $\tilde{Q}$ and that the regulating action of $\tilde{Q}$ is “proportional” to the residual signal f which, in some sense, indicates the modeling mismatch. Hence, it is not a surprise that the new controller structure could provide a robust regulation with much less compromised optimal performance achieved by LQG control, albeit at the expense of higher controller order overall.

It is noted that $\tilde{Q}$ could be designed through other approaches in practice, for example, as a predictive controller, to further improve the robustness of the LQG performance for the closed-loop system. Essentially, the role played by the observer in $\tilde{Q}$ structure can be deemed as serving certain kind of “model-guided” function, hence, leaving the window open for the use of more complicated model or even a nonlinear model in the case of a nonlinear plant being addressed.

The structure of “multi-block” implementation of Youla-Kučera parameterization in Fig. 3 could potentially be extended to other control designs than LQG and $\mathcal{H}_\infty$, thanks to the complementary nature of the controller $C(s)$ and the $\tilde{Q}$ -regulation, as well as the extra design freedom brought in by $\tilde{Q}$. It would then be interesting, both theoretically and practically, to explore different combined designs of $\tilde{Q}$ and the controller $C(s)$ to illustrate the effectiveness of this complementary paradigm.

Multiple Mobile Robots

Filippo Arrichiello

Department of Electrical and Information Engineering, University of Cassino and Southern Lazio, Cassino, Italy

Abstract

This section focuses on multiple mobile robots, i.e., team of grounded, aerial, or marine autonomous mobile robots performing cooperative missions. To the purpose, the section provides a brief literature review and an overview about some of the main aspects related to the control of multiple mobile robots, as their possible aims, applications, and control architectures.

Keywords

Multi-robot systems · Control architecture · Robotic swarms · Multi-agent systems

Introduction

In the recent years, several research efforts have been directed toward the use of multiple mobile robots (MMRs). The interest in this field is well justified by the advantages that such systems present with respect to single autonomous robots, and it is well supported by the improvements in the technologies that allow the interaction and the integration among multiple robotic systems. Generally speaking, the term MMRs includes different typologies of robotic systems; in this context, the term will be used referring to a team of cooperating grounded, aerial, or marine autonomous mobile robots.

One of the main motivations for employing MMRs can be found in the possibility they offer in terms of improvement of the system effectiveness, that is, with respect to a single autonomous robot or to a team of not cooperating robots, a

MMRs system can better perform a mission in terms of time and quality, it can achieve tasks not executable with a single robot (e.g., moving a large object), or it can take advantages of distributed sensing and actuation. Moreover, instead of building and using a single powerful robot, a multi-robot solution can be easier and cheaper, it can provide flexibility to the execution of the task, and it can make the system tolerant to possible robots' faults.

The term *cooperation* underlines the interaction or the integration among multiple mobile robots; that means that the robots have to communicate, exchange information, or interact in some way with each other in order to achieve an overall common objective. The meaning of cooperation among robots has been widely discussed in the scientific community, and different definitions have been proposed. Three of them, reported in Cao et al. (1997), are: cooperation is

- “a joint collaborative behavior that is directed toward some goal in which there is a common interest or reward”
- “a form of interaction, usually based on communication”
- “joining together for doing something that creates a progressive result such as increasing performance or saving time”.

The first definition leads to the study of *task decomposition*, *task allocation*, and other *distributed artificial intelligence* issues; the second underlines the requirements of *communication* or other common resources; finally, the third is related to the *performance measurements* of *cooperation*, such as speedup in time to complete a task. Moreover, these definitions point out different aspects of cooperation: the task, the mechanism of cooperation, and the system performance.

The *task* can be considered as the aim of the multi-robot system; thus, it changes depending on the different applications and on the typologies of the MMRs system. The task is usually decomposed in elementary sub-tasks (task decomposition) to make it easier to understand and execute.

These sub-tasks can be distributed among multiple resources (task allocation), while the overall behavior of the system depends on how these sub-tasks are recombined to obtain the final action or motion command for the system.

The *mechanism of cooperation* represents the logic that originates the cooperation, and it may depend on the control architectures and strategies, on aspects of the tasks specification, or on the interaction dynamics. The MMRs system has to exhibit a collective behavior, or a set of actions that accomplishes the same behavior that was required for the single more complex robot; thus, the members of the MMRs system have to communicate directly through an explicit communication channel or indirectly through one robot sensing the others.

The *system performance* can be represented through characteristics, e.g., mission execution time, computational complexity, robustness, and fault tolerance, and it may depend on the global structure of the system, e.g., typologies of the system, control architectures and strategies, task definition and actuation, and communication characteristics.

Due to the multiple aspects that characterize a MMRs system, the progress of the research in cooperative robotics has concerned most of these aspects simultaneously. Thus, characteristics like control architectures and algorithms, differentiation among the robots of the team, communication structures, resource conflicts, and mechanisms of cooperation or learning have been often developed by the scientific community in an integrated way. This strong correlation makes hard a classification focused on single aspects; thus, different works have been presented only to introduce a taxonomy valid for the field. The work in Dudek et al. (1996) presents a taxonomy for multi-agent robotic systems that proposes a classification depending on the size of the team (how many robots compose the team), the communication parameters (communication range, topology, and bandwidth), the reconfigurability of the team, the processing ability of each member, and the composition of the team (homogeneous vs. heterogeneous robots). The work in Farinelli

et al. (2004) presents a classification based on different levels of coordination (unaware, aware but non-coordinated, weakly coordinated, strongly coordinated systems), and it introduces a classification based on the so-called coordination dimensions (cooperation, knowledge, coordination, organization) and system dimensions (communication, team composition, system architectures, and team size). Finally, the work in Gerkey and Mataric (2004) presents a taxonomy based on coordination mechanisms and on multi-robot task allocation.

Aims and Applications

The large variety of MMRs developed in the recent years makes possible a distinction based on the typologies of vehicles and on their missions. The first applications concerned systems composed of grounded mobile robots (e.g., see Fig. 1) that are autonomous robots with wheels or crawlers. Such robots can be built both for indoor environments (i.e., buildings, museums, and laboratories) (Noreils 1993; Howard et al. 2006) and for outdoor environments (i.e., open space with terrain, grass, or rocky floor) (Huntsberger et al. 2003; Carpin and Parker 2002), and they result the most commonly used ones.

However, in the latest years, several applications with different kinds of vehicles have been proposed in the literature, as multi-robot systems composed of unmanned aerial vehicles (AUVs) (Beard et al. 2001; Stipanovic et al.

2004; Kushleyev et al. 2013; Spurný et al. 2019), underwater autonomous vehicles (AUVs) (Fiorelli et al. 2004; Stilwell and Bishop 2000; Abreu et al. 2016), or fleets of marine crafts (Encarnacao and Pascoal 2001; Ihle et al. 2006; Børhaug et al. 2010) (see Figs. 2 and 3).

The applications of multi-robot systems may involve different fields, e.g., industrial, military, service robotics, and research and study of biological systems, and they may concern largely different kinds of missions as exploration, box pushing, military operation, navigation in unstructured environment, traffic control, entertainment, simulations of biological systems, and environmental monitoring.

Among the possible applications, a typical one concerns the possibility to move large objects using multiple robots (sometimes with manipulators on board). A single robot, in fact, may be not powerful enough to push alone the

Multiple Mobile Robots, Fig. 1 Multiple grounded mobile robots

Multiple Mobile Robots, Fig. 3 Multiple underwater mobile robots. (Courtesy of Graal Tech)

object, and it can be unable to apply forces in all the generalized directions. Thus, a multi-robot solution can be useful to share the needed power among multiple robots, and, using multiple contact points, it may permit to apply forces in the all generalized directions. On the other hand, the multi-robot solution needs for a strong coordination among the robots; that means the robots have to share information about their relative positions and about the shape and position of the object. To achieve this kind of mission (generally called box-pushing mission), different MMRs systems have been presented in the literature, e.g., in Mataric et al. (1995) where some experimental results of box pushing using two-legged robots are presented or in Yamada and Saito (2001) where a team of differential-drive mobile robots performs the box-pushing mission without explicit communication. The work in Wang et al. (2003) focuses on function distribution and behavior design for cooperative object handling with multiple mobile robots; moreover, the work in Yamashita et al. (2003) presents a motion-planning method for multiple-mobile robots to cooperatively transport large objects, while the work in Tanner et al. (2003) presents an approach to carry a deformable object by means of two mobile robots with manipulators on board.

Another common kind of applications concerns the possibility to use a team of cooperating robots to explore an unknown environment and build its map. To achieve this mission in a cooperative way, the robots must be coordinated to explore different parts of the environment and share partial maps elaborated by each single robot to build the global map of the environment; as a consequence, they can explore the environment in reduced amount of time with respect to a single robot. Simultaneously, the robots have to localize themselves with respect to the environment to correctly achieve the mission and merge the partial maps. This kind of applications, known in the literature as simultaneous localization and mapping (SLAM), has been object of extensive research efforts, and different solutions have been proposed. For example, in Rekleitis et al. (2001) a team of two robots collaborate to explore and map a large environment, and, sens-

ing one another, they try to reduce the odometric errors and also coping with obstacles with hard-to-sense reflectance characteristics. The work in Zlot et al. (2002) proposes an approach for exploration and mapping that exploits a market architecture in order to maximize information gain while minimizing incurred cost, while the work in Burgard et al. (2005) presents experiments with a team of up to three heterogeneous robots used to reduce exploration time also in situation where the communication ranges of the robots are limited.

Part of the works in cooperative mobile robotics has a biological inspiration; this kind of approaches began after the introduction of the robotics paradigm of behavior-based control (Arkin 1989, 1998; Brooks 1986) that can be described by the relationship between the three primitives of robotics: sense, plan, and act. The behavior-based paradigm for mobile robotics has been useful for robotic researchers to examine the social characteristics of insects and animals and to apply these findings to the design of multi-robot systems. Another common application is the use of elementary control rules of various biological animals (e.g., ants, bees, birds, and fishes) to reproduce a similar behavior (e.g., foraging, flocking, homing, dispersing Mataric 1995) in cooperative robotic systems. The first works have been motivated by application in computer graphics, e.g., in 1986, Reynolds (1987) made a computer model for coordinating animal motion as bird flocks or fish schools. This pioneer work inspired significant efforts in the study of group behaviors (Parker et al. 1993; Mataric 1992; Kube and Zhang 1993) and then in the study of multi-robot formations (Wang 1991; Parker 1996; Balch and Arkin 1998).

Control Architectures and Strategies

Coordination and interaction of multiple intelligent agents have been actively studied in the field of distributed artificial intelligence since the early 1970s mainly concerning problems involving software agents. Then, in the late 1980s and early 1990s, the robotic research community became very active in the cooperative robotic

field with projects like CEBOT, SWARM, and ALLIANCE.

The works in Fukuda and Nakagawa (1988) and Fukuda et al. (1989) present the distributed hierarchical system CEBOT, inspired by cellular organization of biological entities. Such architecture results to be dynamically reconfigurable, that is, the cells are able to communicate with each other, approach, connect, and separate automatically. Moreover, if a cell is damaged, then it can be automatically repaired or replaced to maintain the system functions.

The work in Beni (1988) presents a distributed system with a large number of autonomous robots (which in the successive works has been named SWARM) that is also based on cellular robotics, and it allows the robots to accomplish cooperation tasks like assembly, communication, and computing.

The work in Parker (1994, 1996) presents a behavior-based architecture for cooperative control, called ALLIANCE. Such architecture has been developed in order to study the cooperation in an heterogeneous, small-/medium-size team of robots that should result in a fault-tolerant, reliable, and adaptive mechanism for cooperative robot control.

Successively, largely different kinds of control architectures for MMRs have been presented in literature; however, the main distinction can be done between centralized and decentralized systems. In centralized systems, a core unit collects and manages information about the environment to coordinate and control the motion of the robots and to guarantee the correct achievement of the mission. In such approaches, the core unit plays a fundamental role since it manages the whole system, i.e., it has to coordinate the information received by the distributed sensors, to manage the global information about the environment, to take all the eventual decisions, and to communicate with all the robots of the team; thus, it should be powerful enough to satisfy all the technological requirement. In decentralized approaches, instead, the resources are distributed among all the robots. Each vehicle uses its own sensors to extrapolate local information of the environment and the relative positions of the close robots to take its own decisions; moreover, each vehicle

can communicate and share information only with the close vehicles, and it is aimed at achieving only a part of the global mission.

Advantages and disadvantages of centralized and decentralized systems have been object of several discussions in the scientific community. Centralized systems, for example, can manage global information and optimize the coordination among the robots and the accomplishment of the mission; moreover, they can easily manage faults of some of the robots. On the other hand, the core unit may represent a weakness of the system; in fact, it can be the bottleneck of the system both for computational and communication time requirements; moreover, its eventual fault compromises the whole system. Decentralized systems, instead, permit to take all the advantages of distributed sensing and actuation, i.e., they make it possible to use less powerful robots or to use more cheaper sensors; they permit to optimize the allocation of the resources and to equip the robots of the team with different actuation and sensor systems; moreover, decentralized systems can easily result in tolerance to possible vehicle faults. On the other hand, within decentralized systems it is difficult to coordinate the robots and optimize the execution of the mission, and problems like global localization and mapping and communication bandwidth represent limits of this system.

In practice, many systems are not strictly centralized/decentralized. In fact, many largely decentralized architectures utilized leader agents (e.g., in Tanner et al. 2004); moreover, different hybrid centralized/decentralized architectures were presented to take partial advantages of both the typologies (Antonelli 2013); e.g., the hybrid architectures in Feddema et al. (2002), Das et al. (2002), and Stilwell et al. (2005) have central planners that perform a high-level control over mostly autonomous robots.

Beyond the architectures, different control strategies for multi-robot systems have been proposed in literature. These strategies, aimed at elaborating the motion directives to each vehicle, may differ both for mathematical characteristics and implementation aspects. As a limited set of examples, the use of control graphs to address the problem of changing the platoon formation

is discussed in Desai et al. (1999). The work in Belta and Kumar (2004) presents a formal abstraction-based approach to control a large number of robots required to move as a group; this mathematical approach is based on Lie algebra, and it is aimed at controlling the shape of the team of robots that should be kept inside an ellipsoid or rectangular area. The work in Tabuada et al. (2005) focuses on formation motion feasibility of multi-agent systems, that is, it focuses on the algebraic conditions that guarantee formation feasibility given the individual agent kinematics. The paper (Vig and Adams 2006) presents experimental results of coalition formation of a multi-robot system while simultaneously performing heterogeneous missions. Several recent control solutions rely on graph theoretic methods for multi-multi-agent networks (Mesbahi et al. 2010) or on consensus-based distributed algorithm (Ren and Randal 2008).

Future Directions

The research in multi-robot systems has matured to the point where systems with hundreds of robots (swarms) have been proposed (Parker 2003; Konolige et al. 2005; Howard et al. 2006). However, to achieve a cooperative task, the robots have to share information; thus, the increase of the team dimension directly requires an increase in the needed computational and communication resources, and it may introduce static and dynamic scalability issues. Specifically, a system is statically scalable when the control architecture can be kept exactly the same whether thousands of robots are deployed or only few are used; a system is dynamically scalable when robots can be added to or removed from the system on the fly, and they may also have the ability to reallocate and redistribute themselves in a self-organized way. In this sense, scalability still represents a limit for most of the actual platforms and control solutions for MMRs, and it can still represent an open issue for the research in this field. Furthermore, other future research directions can also be found in the field

of distributed planning and decision-making, cooperative/collective learning for multi-robot system, cloud robotics, optimal control and optimization methods, and performance evaluation and benchmarking for MMRs.

Multiscale Multivariate Statistical Process Control

Julian Morris

School of Chemical Engineering and Advanced Materials, Centre for Process Analytics and Control Technology, Newcastle University, Newcastle Upon Tyne, UK

Abstract

Dynamic processes, both continuous and batch, are characterised by autocorrelated measurements which are allied to the effects

of process dynamics and disturbances. The common multivariate statistical process control (MSPC) approaches have been to use principal component analysis (PCA) or projection to latent structures (PLS) to build a model that captures the simultaneous correlations amongst the variables, but that ignores the serial correlation in the data during normal operations. Under such conditions it is difficult to perform efficient fault detection and diagnosis. An alternative approach to account for the process dynamics in MSPC is to use multiresolution analysis (MRA) by way of wavelet decomposition. Here, the individual measurements are decomposed into different scales (or frequencies) and the signals in each decomposed scale are then used for MSP which provides an indirect way of handling process dynamics.

MSPCA

Definition

Multiscale principal component analysis (MSPCA) and its extension multiscale projection to latent structures (MSPLS) combine the abilities of these multivariate tools to de-correlate the variables by extracting linear relationships with that of wavelet analysis, to extract deterministic features and approximately de-correlate autocorrelated measurements. Multiscale modeling makes use of the wavelet transform which allows a signal (measurement) to be viewed in multiple resolutions with each resolution representing a different frequency. That is, wavelet transform allows complex information to be decomposed

into basic components at different positions and scales.

Motivation and Background

One of the drawbacks of the conventional PCA (or PLS)-based MSPC is that although the PCA/PLS model captures the correlations among the variables, it ignores the serial (auto)correlation in the process variables and measurements. One way to overcome this issue is to include time-lagged variables in the PCA or PLS model. In this way, PCA and PLS will explicitly model both the correlations among the variables and the serial correlations in the individual variables. The impact is an increase in the number principal components required, but the multivariate monitoring model will be able to detect any changes in the serial correlation of the variables as well as changes in relationships among the variables. This article focuses on multiscale-multiway PCA using batchwise data unfolding. However, the methodology can equally be applied to PLS-based process performance monitoring (MSPC).

In multivariate statistical process control (MSPC), the multivariate statistical techniques of principle component analysis (PCA) and projection to latent structures {Partial Least Squares} (PLS) together with monitoring metrics based on Hotelling's T^2 (directly related to the Mahalanobis distance that monitors the fit of new observations to the model space) and the squared prediction error (SPE) or Q statistic (that monitors the residual space-model mismatch) are used to simultaneously monitor the process variables (Kourti and MacGregor 1996; Qin 2003). A recent survey provides an excellent state-of-the-art review of the methods and applications of data-driven fault detection and diagnosis that have been developed over the last two decades (Qin 2012).

Process measurements typically exhibit multiscale behavior as a consequence of representing the cumulative effect of a number of underlying process phenomena including process dynamics, measurement noise, and disturbances. To

address these issues, methodologies are required to address (i) the multiscale nature of process data and (ii) the inability of some existing algorithms to handle autocorrelation. One approach is through the use of multiresolution analysis and wavelets Mallat (1998). Informative discussions and application studies related to using multiresolution analysis and wavelet decompositions to enhance PCA-based process monitoring and fault detection have been presented, for example, by Bakshi (1998), Misra et al. (2002), Aradhye et al. (2003), Lu et al. (2003), Yoon and MacGregor (2004) and Reis and Saraiva (2006). Yoon and MacGregor in their comprehensive MSPCA study discussed their approach in the context of other multiscale approaches and illustrated the methodology using simulated data from a continuous stirred-tank reactor system. A major contribution of the paper was to extend fault isolation methods based on contribution plots to multiscale PCA approaches. Although some 9 years old, Ganesan et al. (2004) provided review of wavelet-based multiscale statistical process monitoring.

The Approach

Multiresolution analysis (MRA) provides the theoretical basis for the derivation of a computationally efficient algorithm for the wavelet transform Mallat (1998). MRA allows the dynamic aspects of the data in to be taken into account in MSPC. The individual signals are decomposed into different scales (frequencies), and data in each decomposed scale are then used for MSPC which provides an indirect approach to handling process dynamics. Multiscale MSPC (MSPCA) enables the simultaneous extraction of process correlations across data as well as accounting for autocorrelation within sensor data. In this way, it captures correlations among the process variables made by various events occurring at different scales.

MSPCA calculates the principal components of wavelet coefficients at each scale and combines these at the relevant wavelet scales. Due to its multiscale nature, MSPCA is very use-

ful for the modeling of data containing contributions from events whose behavior changes over both time and frequency. Process monitoring by MSPCA, and process prediction by MSPLS, involves combining those scales where significant events are detected. Approximate decorrelation of wavelet coefficients also makes MSPCA effective for the monitoring of autocorrelated measurements.

The Algorithm

Wavelets are a family of basis functions that provide a mapping from the time domain to the time-frequency domain. They can be used to decompose the signal into different resolutions by projecting onto the corresponding wavelet basis functions using multiresolution analysis (MRA). A wavelet set is constructed from a fundamental basis function or the mother wavelet by a process of translation and dilation. The wavelet set is defined as wavelet analysis which provides methodologies for the extraction of the time and frequency content of a signal. Conventional frequency analysis based on the Fourier transform consists of decomposing a signal into sine waves of different frequencies. Wavelet analysis decomposes the original signal in a similar manner. The major difference is that while Fourier analysis uses sine waves of infinite length, multiresolution analysis uses waveforms of finite length. The finite length of the wavelets allows them to describe local events in both the time and frequency domain.

The wavelet transform, an extension to the Fourier transform, projects the original signal down onto wavelet basis functions, providing a mapping from the time domain to the timescale plane. The wavelet functions, which are localized in the time and frequency domain, are obtained from a single prototype wavelet, the *mother wavelet*, by dilation and translation. The wavelet set is defined as

$$\psi_{a,b}(t) = \frac{1}{\sqrt{|a|}} \psi\left(\frac{t-b}{a}\right)$$

where ψ is the mother wavelet function, a the dilation parameter, and b the translation parameters, and the factor $\frac{1}{\sqrt{|a|}}$ is used to ensure that each wavelet function has the same energy as the mother wavelet. The discrete wavelet transform with dyadic dilation and translation is used in this overview. A definition of continuous and discrete wavelet transforms can be found in Daubechies (1992). In the discrete case, the dilation and translation parameters are discretized as $a = a_0^m$ and $b = kb_0a_0^m$. If $a_0 = 2$ and $b_0 = 1$, a *dyadic* dilation and translation is carried out; however, a_0 and b_0 are not restricted to these values. The discrete wavelet form, which is widely used in process monitoring and chemical signal analysis, is

$$\psi_{jk}(t) = a_0^{-j/2} \psi(a_0^{-j}t - kb_0)$$

A recursive algorithm for wavelet decomposition and the reconstruction of a discrete signal of dyadic length is often used Mallat (1998) and is known as the pyramid algorithm. The fast discrete wavelet decomposition consists of three components, low-pass filters $L(n)$, high-pass filters $H(n)$, and dyadic decimation. By passing the input signal through this pair of filters, the projection of the original signal onto the scaling and wavelet functions for the multiresolution analysis is performed. Dyadic decimation, or down-sampling, removes every odd member of a sequence, thus halving the original number of samples. The low-pass filter resembles a moving average, while the high-pass filter extracts the detailed information contained in the signal. The discrete wavelet transform operates by taking a sequence of values, applying $L(n)$ and $H(n)$ and then repeating this same procedure to the approximation coefficients. In this way, the original signal vector is *smoothed and halved* through L , and the vector of approximation coefficients is again *smoothed and halved* through L . Successive application of the low-pass filter results in the approximation coefficients, becoming an increasingly smooth version of the original signal. At the same time as smoothing the signal, each iteration extracts

Multiscale Multivariate Statistical Process Control, Fig. 1 Schematic of multiresolution wavelet decomposition

the high frequency information in the data. The repeated application of L , followed by H is, in effect, a band-pass filter. The result of applying high-/low-pass filters to a signal is a set of coefficients describing the details of the signals $\mathbf{D}_L$ and a second set describing the approximations of the signals $\mathbf{A}_L$. The original signal s can then be represented by

$$x(t) = \sum_{j=1}^L D_j(t) + A_L(t)$$

where D_j and A_j are referred to as the j th level wavelet details and approximation, respectively.

Figure 1 shows schematically the multi-resolution-based wavelet decomposition.

One of the most popular choices of wavelets are those of the Daubechies' family. These wavelets are compactly supported in the time domain and have good frequency domain decay. Moreover, Daubechies' wavelets (DaubN) possess a different type of smoothness which is determined by the vanishing moments N . This makes it possible to match the wavelet smoothness to the smoothness of the signals to be analyzed. The signal can then be decomposed into its contributions from multiple scales

as a weighted sum of dyadically discretized orthonormal basis functions:

$$x(t) = \sum_{m=1}^L \sum_{k=1}^N d_{mk} \psi_{mk}(t) + \sum_{k=1}^N a_{lk} \phi_{lk}(t)$$

where $x(t)$ represents the process measurements, d_{mk} represents the wavelet or detail signal coefficient at scale m and location k , and a_{lk} represent the scaled signal or scaling function coefficient of $\phi(t)$ at the coarsest scale L and location k . The scaling function, or father wavelet, ϕ_{mk} captures the low-frequency content of the original signal that is not captured by wavelets at the corresponding or finer scales.

The wavelet transformation is applied to decompose a multivariate signal $\mathbf{X}$ into its approximate, $\mathbf{A}_1$ to $\mathbf{A}_L$, and detail, $\mathbf{D}_1$ to $\mathbf{D}_L$, coefficients for the first to L th level, respectively. For more information, see Bakshi (1998), Misra et al. (2002) and Aradhye et al. (2003). Figure 2 shows a schematic representation of a typical MSPCA multivariate statistical process control scheme.

An example of the application of multiway-multiscale MPCA to a benchmark-fed batch

Multiscale Multivariate Statistical Process Control, Fig. 2 Schematic representation of multiscale PCA-based MSPC

Multiscale Multivariate Statistical Process Control, Fig. 3 Multiscale-multiway batch process monitoring scheme

fermentation process (Birol et al. <http://www.chee.iit.edu~control/software.html>) was presented by Alawi and Morris (2007). The application used a combination of multiblock statistical modeling approaches together with multiscale-multiway batch monitoring. Figure 3 shows the multiscale-multiway monitoring scheme for process monitoring and fault detection. At every time point, the batch process variables are decomposed into scales to the wavelet domain and then reconstructed back to the time domain. The scales/details and the approximations are collected into separate matrices (blocks). Multiblock PCA is then applied to the wavelets details and approximation. Fault detection based on the T_s^2 and Q_s statistics was used along with contribution plots incorporating confidence bounds to enhance fault diagnosis.

Figure 4 compares the monitoring statistics for the multiscale-multiway PCA and conventional multiway PCA for a slowly drifting sensor fault showing the potential for multiscale MPCA (MSPCA) in being able to detect faster subtle process and sensor faults than conventional multiway MSPC. It is noted that sensor drift is confined to one scale band at low frequency. It has been observed that multiscale approaches appear to provide little improvement if a fault effect is spread over more than one frequency band or the fault effect occurs mainly in a scale with dominant variance. Thus, a monitoring method that gives the best detection and identification of faults will depend on the fault characteristics with multiscale approaches, providing an advantage when the faults localized in frequency or that appear in scales that normally have small variance.

Multiscale Multivariate Statistical Process Control, Fig. 4 Comparison of MPCA and multiscale MSPCA for a range of subtle sensor drift faults magnitude ω against fault detection delay

Other Applications of Multiscale MPCA

There have a number of nonlinear extensions. For example, multiscale PLS approaches have been developed, e.g., Teppola and Minkkinen (2000) and Lee et al. (2009). Nonlinear approaches have also been explored. For example, Lee et al. (2004) proposed a batch monitoring approach using multiway kernel principal component analysis, Shao et al. (1999) proposed a wavelet-based nonlinear PCA algorithm, Choi et al. (2008) described a study of a kernel-based MSPCA algorithm for nonlinear multiscale monitoring, and most recently Zhang and Ma (2011) compared fault diagnosis of nonlinear processes using multiscale KPCA and multiscale KPLS. Wavelet multiscale approaches have also been widely discussed in spectroscopic data processing (Shao et al. 2004).

Multi-vehicle Routing

Emilio Frazzoli¹ and Marco Pavone²

¹Massachusetts Institute of Technology,
Cambridge, MA, USA

²Stanford University, Stanford, CA, USA

Abstract

Multi-vehicle routing problems in systems and control theory are concerned with the design of control policies to coordinate several vehicles moving in a metric space, in order to complete spatially localized, exogenously generated tasks in an efficient way. Control policies depend on several factors, including the definition of the tasks, of the task generation process, of the vehicle dynamics and constraints, of the information available to the vehicles, and of the performance objective. Ensuring the stability of the system, i.e., the uniform boundedness of the number of outstanding tasks, is a primary concern. Typical performance objectives are represented by measures of quality of service, such as the average or worst-case time a task spends in the system before being completed or the percentage of tasks that are completed before certain deadlines. The scalability of the control policies to large groups of vehicles often drives the choice of the information structure, requiring distributed computation.

Cooperative control · Decentralized control · Dynamic routing · Networked robots · Task allocation

Introduction

Multi-vehicle routing problems in systems and control theory are concerned with the design of control policies to coordinate several vehicles moving in a metric space, in order to complete spatially localized, exogenously generated tasks in an efficient way. Key features of the problem are that tasks arrive *sequentially* over time and planning algorithms should provide *control policies* (in contrast to preplanned routes) that prescribe how the routes should be updated as a function of those inputs that change in real time. This problem is usually referred to as dynamic vehicle routing (DVR). In DVR problems, ensuring the stability of the system, i.e., the uniform boundedness of the number of outstanding tasks, is a primary concern.

Motivation and Background

As a motivating example, consider the following scenario: a team of unmanned aerial vehicles (UAVs) is responsible for investigating possible threats over a region of interest. As possible threats are detected, by intelligence, high-altitude or orbiting platforms, or by ground sensor networks, one of the UAVs must visit its location and investigate the cause of the alarm, in order to enable an appropriate response if necessary. Performing this task may require the UAV not only to fly to the possible threat's location but also to spend additional time on site. The objective is to minimize the average time between the appearance of a possible threat and the time one of the UAVs completes the close-range inspection task. Variations may include priority levels, time windows during which the inspection task must be completed, and sensors with limited range.

In order to perform the required mission, the UAVs (or, more in general, mission control) need to repeatedly solve three *coupled* decision-making problems:

1. **Task allocation:** which UAV shall pursue each task? What policy is used to assign tasks to UAVs? How often should the assignment be revised?

2. **Service scheduling:** given the list of tasks to be pursued, what is the most efficient ordering of these tasks?
3. **Loitering paths:** what should UAVs without pending assignments do?

The optimization process must take into account, for example, algebraic or differential constraints (such as obstacle avoidance or bounded curvature, respectively), sensing constraints, communication constraints, and energy constraints. Furthermore, one might require a decentralized control architecture.

DVR problems, including the above UAV routing problem, are generally *intractable* due to their multifaceted combinatorial, differential, and stochastic nature, and consequently solution approaches have been devised that look either at heuristic algorithms or at approximation algorithms with some guarantee on their performance.

Related Problems

DVR problems represent the dynamic counterpart of the well-known static vehicle routing problem (VRP), whereby (i) a team of n vehicles is required to service a set of n_T “static” tasks in a metric space, (ii) each task requires a certain amount of on-site service, (iii) and the goal is to compute a set of routes that minimizes the cost of servicing the tasks; see Toth and Vigo (2001) for a thorough introduction to this problem. The VRP is *static* in the sense that vehicle routes are computed assuming that no new tasks arrive. The VRP is an important research topic in the operations research community.

Approaches for Multi-vehicle Routing

Broadly speaking, there are three main approaches available in the literature to tackle dynamic vehicle routing problems. The first approach relies on heuristic algorithms. In the second approach, called “competitive analysis approach,” routing policies are designed to minimize the *worst-case* ratio between their performance and the performance of an optimal off-line algorithm

which has a priori knowledge of the entire input sequence. In the third approach, the routing problem is embedded within the framework of queueing theory. Routing policies are then designed to *stabilize* the system in terms of uniform boundedness of the number of outstanding tasks and to minimize typical queueing-theoretical cost functions such as the *expected time* the tasks remain in the queue. Since the generation of tasks and motion of the vehicles is within an Euclidean space, one can refer to this third approach as “spatial queueing theory.”

Heuristic Approach

The main aspect of the heuristic approach is that routing algorithms are evaluated primarily via numerical, statistical and experimental studies, and formal performance guarantees are not available. A naïve, yet reasonable approach to design a heuristic algorithm for DVR would be to adapt classic queueing policies. However, perhaps surprisingly, this adaptation is not at all straightforward. For example, routing algorithms based on a first-come-first-served policy, whereby tasks are fulfilled in the order in which they arrive, are unable to stabilize the system for all stabilizable task arrival rates, in the sense that with such routing algorithms the average number of tasks grows over time without bound, even though there exist alternative routing algorithms that would maintain the number of tasks uniformly bounded (Bertsimas and van Ryzin 1991).

The most widely applied approach is to combine static routing methods (e.g., VRP-like methods, nearest neighbor strategies, or genetic algorithms) and sequential re-optimization, where the re-optimization horizon is chosen heuristically. In particular, greedy nearest neighbor strategies, whose formal characterization still represents an open problem, are known to perform particularly well in some notable cases (Bertsimas and van Ryzin 1991). However, the joint selection of a static routing method and of the re-optimization horizon in the presence of vehicle and task constraints (e.g., differential motion constraints, or task priorities) makes the application of this

approach far from trivial. For example, one can show that an erroneous selection of the re-optimization horizon can lead to pathological scenarios where no task *ever* receives service (Pavone 2010). Additionally, performance criteria in dynamic settings commonly differ from those of the corresponding static problems. For example, in a dynamic setting, the time needed to complete a task may be a more important factor than the total vehicle travel cost.

Competitive Analysis Approach

The distinctive feature of the competitive analysis approach is the method used to evaluate an algorithm's performance, which is called *competitive analysis*. In competitive analysis, the performance of a (causal) algorithm is compared to the performance of a corresponding off-line algorithm (i.e., a non-causal algorithm that has a priori knowledge of the entire input) in the worst-case scenario. Specifically, an algorithm is c -competitive if its cost on *any* problem instance is at most c times the cost of an optimal off-line algorithm:

$$\text{Cost}_{\text{causal}}(I) \leq c \text{Cost}_{\text{optimal off-line}}(I),$$

for all problem instances I .

In the recent past, several dynamic vehicle routing problems have been successfully studied in this framework, under the name of the online traveling repairman problem (Jaillet and Wagner 2006), and many interesting insights have been obtained. However, the competitive analysis approach has some potential disadvantages. First, competitive analysis is a *worst-case* analysis; hence, the results are often overly pessimistic for normal problem instances, and potential statistical information about the problem (e.g., knowledge of the spatial distribution of future tasks) is often neglected. Second, the worst-case analysis usually requires a *finite* horizon problem formulation, which precludes the study of useful properties such as stability. Third, competitive analysis is used to bound the performance relative to an optimal *off-line* algorithm, which, by being

non-causal, does *not* belong to the feasible set of routing algorithms one is optimizing over. Hence, with this approach one minimizes the “cost of causality” in the worst-case scenario, but not necessarily the worst-case cost (which would require comparison with an optimal *causal* routing algorithm). Finally, many important real-world constraints for DVR, such as time windows, priorities, differential constraints on vehicle's motion, and the requirement of teams to fulfill a task, have so far proved to be too complex to be considered in the competitive analysis framework (Golden et al. 2008, page 206). Some of these drawbacks have been recently addressed by Van Hentenryck et al. (2009) where a combined stochastic and competitive analysis approach is proposed for a general class of combinatorial optimization problems and is analyzed under some technical assumptions.

Spatial Queueing Theory

Spatial queueing theory embeds the dynamic vehicle routing problem within the framework of queueing theory. Spatial queueing theory consists of three main steps, namely, development of a spatial queueing model, establishment of fundamental limitations of performance, and design of algorithms with performance guarantees. More specifically, the formulation of a model entails detailing four main aspects:

1. A model for the *dynamic* component of the environment: this is usually achieved by assuming that new events are generated (either adversarially or stochastically) by an exogenous process.
2. A model for targets/tasks: tasks are usually modeled as points in a physical environment distributed according to some (possibly unknown) distribution, might require a certain level of on-site service time, and can be subject to a variety of constraints, e.g., time windows, priorities, etc.
3. A model for the vehicles and their motion: besides their number, one needs to specify whether the vehicles are subject to algebraic (e.g., obstacles) or differential (e.g., min-

imum turning radius) constraints, sensing constraints, and fuel constraints. Also, the control could be centralized (i.e., coordinated by a central station) or decentralized and subject to communication constraints.

4. Performance criterion: examples include the minimization of the waiting time before service, loss probabilities, expectation-variance analysis, etc.

Once the model is formulated, one seeks to characterize fundamental limitations of performance (in the form of lower bounds for the best achievable cost); the purpose of this step is essentially twofold: it allows the quantification of the degree of optimality of a routing algorithm and provides structural insights into the problem. As for the last step, the design of a routing algorithm usually relies on a careful combination of static routing methods with sequential re-optimization. Desirable properties for the static methods are the following: (i) the static problem can be solved (at least approximately) in polynomial time and (ii) the static method is amenable to a statistical characterization (this is essential for the computation of performance bounds). Formal performance guarantees on a routing algorithm are then obtained by quantifying the ratio between an upper bound on the cost delivered by that algorithm and a lower bound for the best achievable cost. Such a ratio, being an estimate of the degree of optimality of the algorithm, should be close to one and possibly independent of system parameters. The proposed algorithms are finally evaluated via numerical, statistical and experimental studies, including Monte-Carlo comparisons with alternative approaches.

An interesting feature of this approach is that the performance analysis usually yields scaling laws for the quality of service in terms of model data, which can be used as useful guidelines to select system parameters when feasible (e.g., number of vehicles).

In order to make the model tractable, the arrival process of tasks is assumed stationary (with possibly unknown parameters) with

statistically independent arrival times. These assumptions, however, can be unrealistic in some scenarios, in which case the competitive analysis approach may represent a better alternative. From a technical standpoint, one should note that spatial queueing models are *inherently* different from traditional, nonspatial queueing models. The main reason is that in spatial queueing models, the “service time” per task has both a *travel* and an *on-site* component. Although the on-site service requirements can often be modeled as “statistically” independent, the travel times are *inherently* statistically coupled. Hence, in contrast to standard queueing models, service times in spatial queueing models are statistically *dependent*, and this deeply affects the solution to the problem.

Pioneering work in this context is that of Bertsimas and van Ryzin (1991), who introduced queueing methods to solve the baseline DVR problem (a vehicle moves along straight lines and visits tasks whose time of arrival, location, and on-site service are stochastic; information about task location is communicated to the vehicle upon task arrival). Next section provides an overview of the application of spatial queueing theory to such simplified DVR problem, referred to in the literature as dynamic traveling repairman problem (DTRP).

Applying Spatial Queueing Theory to DVR Problems

Spatial Queueing Theory Workflow for DTRP

Model

The DTRP, which, incidentally, captures well the salient features of the UAV scenario outlined in the Motivation Section, can be modeled as follows. In a geographical region $\mathcal{Q}$ of area $\mathcal{A}$, a dynamic process generates spatially localized tasks. The process generating tasks is modeled as a spatio-temporal Poisson process, i.e., (i) the time between consecutive generation instants has

an exponential distribution with intensity $\lambda > 0$ and (ii) upon arrival, the locations of tasks are independently and uniformly distributed in $\mathcal{Q}$. The location of the new tasks is assumed to be immediately available to a team of n servicing vehicles. The vehicles provide service in $\mathcal{Q}$, traveling at a speed at most equal to v ; the vehicles are assumed to have unlimited fuel and task-servicing capabilities. Each task requires an independent and identically distributed amount of on-site service with finite mean duration $\bar{s} > 0$. A task is completed when one of the vehicles moves to its location and performs its on-site service. The objective is to design a *routing policy* that maximizes the quality of service delivered by the vehicles in terms of the average steady-state time delay $\bar{T}$ between the generation of a task and the time it is completed (in general, in a dynamic setting, the focus is on the quality of service as perceived by the “end user,” rather than, for example, fuel economies achieved by the vehicles). Other quantities of interest are the average number $\bar{n}_T$ of tasks waiting to be completed and the waiting time $\bar{W}$ of a task before its location is reached by a vehicle. These quantities, however, are related according to $\bar{T} = \bar{W} + \bar{s}$ (by definition) and by Little’s law, stating that $\bar{n}_T = \lambda \bar{W}$, for stable queues.

The system is considered stable if the expected number of waiting tasks is uniformly bounded at all times, or equivalently, that tasks are removed from the system at least at the same rate at which they are generated. In the case at hand, the time to complete a task is the sum of the time to reach its location (which depends on the routing policy) plus the time spent at that location in on-site service (which is independent of the routing policy). Since, by definition, the service time is no shorter than the on-site service time $\bar{s}$, then a weaker necessary condition for stability is $\varrho := \lambda \bar{s} / n < 1$; the quantity ϱ measures the fraction of time the vehicles are performing on-site service. Remarkably, it turns out that this is also a sufficient condition for stability, in the sense that, if this condition is satisfied, one can find a stabilizing policy. Note that this stability condition is independent of the size and shape of $\mathcal{Q}$ and of the speed of the vehicles.

Fundamental Limitations of Performance

To derive lower bounds, the main difficulty consists in bounding (possibly in a statistical sense) the amount of time spent to reach a target location. The derivation of these bounds becomes simpler in asymptotic regimes, i.e., looking at cases when $\varrho \rightarrow 0^+$ and $\varrho \rightarrow 1^-$, which are often called “light-load” and “heavy-load” conditions, respectively.

Consider first the case in which $\varrho \rightarrow 0^+$ (light-load regime). A set of n points is called the n -median of $\mathcal{Q}$ if it globally minimizes the expected distance between a random point sampled uniformly from $\mathcal{Q}$ and the closest point in such set. In other words, the n -median of $\mathcal{Q}$ globally minimizes the function

$$\begin{aligned} H_n(p_1, p_2, \dots, p_n) \\ &:= \mathbb{E} [\min_{k \in \{1, \dots, n\}} \|p_k - q\|] \\ &= \frac{1}{A} \int_{\mathcal{Q}} \min_{k \in \{1, \dots, n\}} \|p_k - q\| dq. \end{aligned}$$

Let H_n^* be the global minimum of this function. Geometric considerations show that H_n^* scales proportionally to $\sqrt{A/n}$.

Incidentally, the n -median of $\mathcal{Q}$ induces a Voronoi partition that is called *Median Voronoi Tessellation*, whose importance will become clear in the next section. Recall that the Voronoi diagram of $\mathcal{Q}$ induced by points $(p_1, \dots, p_n)$ is defined by

$$\begin{aligned} V_i = \left\{ q \in \mathcal{Q} \mid \|q - p_i\| \leq \|q - p_j\|, \forall j \neq i, \right. \\ \left. j \in \{1, \dots, n\} \right\}, \end{aligned}$$

where V_i is the region associated with the i -th “generator” point p_i (see also ► [Optimal Deployment and Spatial Coverage](#)). The distance H_n^* certainly provides a lower bound on the expected distance traveled by a vehicle to reach a task, and hence one obtains the lower bound

$$\bar{T} \geq \frac{H_n^*}{v} + \bar{s}.$$

This lower bound is tight in light-load conditions ($\varrho \rightarrow 0^+$), as it will be seen in the next section.

Consider now the case in which $\varrho \rightarrow 1^-$ (heavy load). Let $\bar{D}$ be the average travel distance per task for some routing policy. By using arguments from geometrical probability (independent of algorithms), one can show that $\bar{D} \geq \beta_2 \sqrt{A}/\sqrt{2n_T}$ as $\varrho \rightarrow 1^-$, where β_2 is a constant that will be specified later. As discussed, for stability, one needs $\bar{s} + \bar{D}/v < n/\lambda$. Combining the stability condition with the bound on the average travel distance per task, one obtains

$$\bar{s} + \frac{\beta_2 \sqrt{A}}{v \sqrt{2n_T}} \leq \frac{n}{\lambda}.$$

Since, by Little's law, $\bar{n}_T = \lambda \bar{W}$ and $\bar{T} = \bar{W} + \bar{s}$, one finally obtains (recall that $\varrho = \lambda \bar{s}/n$):

$$\bar{T} \geq \frac{\beta_2^2 A}{2} \frac{\lambda}{v^2 n^2 (1 - \varrho)^2} + \bar{s}, \quad (\text{as } \varrho \rightarrow 1^-).$$

A salient feature of the above lower bound is that it scales *quadratically* with the number of vehicles (as opposed to the square-root scaling law one has in light-load conditions); note, however, that congestion effects are not included in this model. This bound also shows that the quality of service, which is proportional to $1/(1 - \varrho)^2$, degrades much faster as the target load increases than in nonspatial queueing systems (where the growth rate is proportional to $1/(1 - \varrho)$).

Design of Routing Algorithms

The design of an optimal light-load policy essentially relies on mimicking the proof strategy employed for the light-load lower bound. Specifically, a routing policy whereby (1) one vehicle is assigned to each of the n median locations of $\mathcal{Q}$, (2) new tasks are assigned to the nearest median location and its corresponding vehicle, and (3) each vehicle services tasks according to a first-come-first-served policy is asymptotically optimal, i.e.,

$$\bar{T} \rightarrow \frac{H_n}{v} + \bar{s}, \quad (\text{as } \varrho \rightarrow 0^+).$$

Note that under this strategy “regions of dominance” are implicitly assigned to vehicles according to a Median Voronoi Tessellation.

The heavy-load case is more challenging. Consider, first, the following single-vehicle routing policy, based on a partition of $\mathcal{Q}$ into $p \geq 1$ subregions $\{Q_1, Q_2, \dots, Q_p\}$ of equal area A/p . Such a partition can be obtained, e.g., as sectors centered at the median of $\mathcal{Q}$. Define a cyclic ordering for the subregion, such that, e.g., if the vehicle is in region Q_i , the “next” region is Q_j , where j follows i in the cyclic ordering (in other words, $j = (i + 1) \bmod p$).

1. If there are no outstanding tasks, move to the median of the region Q .
2. Otherwise, visit the “next” subregion; subregions with no tasks are skipped. Compute a minimum-length path from the vehicle's current position through all the outstanding tasks in that subregion. Complete all tasks on this path, ignoring new tasks generated in the meantime. Repeat.

The problem of computing the shortest path through a number of points is related to the well-known traveling salesman problem (TSP). While the TSP is a prototypically hard combinatorial optimization problem, it is well known that the Euclidean version of the problem can be approximated efficiently (Vazirani 2001). Furthermore, the length ETSP(n_T) of a Euclidean TSP through n_T points independently and uniformly sampled in $\mathcal{Q}$ is known to satisfy the following property:

$$\lim_{n_T \rightarrow \infty} \text{ETSP}(n_T)/\sqrt{n_T} = \beta_2 \cdot \sqrt{A}, \quad \text{almost surely,}$$

where $\beta_2 \approx 0.712$ is a constant (the same β_2 constant that appeared in the previous section) (Steele 1990).

It can be shown that, using the above routing policy, the average system time $\bar{T}$ satisfies

$$\bar{T} \leq \gamma(p) \frac{A}{v^2} \frac{\lambda}{(1 - \varrho)^2} + \bar{s}, \quad (\text{as } \varrho \rightarrow 1^-),$$

where $\gamma(1) = \beta_2^2$ and $\gamma(p) \rightarrow \beta_2^2/2$ for large p . These results critically exploit the statistical characterization of the length of an optimal TSP tour. Hence, the proposed policy achieves a quality of service that is arbitrarily close to the optimal one, in the asymptotic regime of heavy load (and, indeed, also of light load).

The above single-vehicle routing policies can be fairly easily lifted to an efficient multi-vehicle routing policy. The key idea (akin to the one in the light-load case) is to (1) partition the workspace into n *regions of dominance* (with disjoint interiors and whose union is $\mathcal{Q}$), (2) assign one vehicle to each region, and (3) have each vehicle follow a single-vehicle routing policy within its own region. This approach leads to the following multi-vehicle routing policy for the DTRP problem:

1. Partition $\mathcal{Q}$ into n regions of dominance of *equal area* and assign one vehicle to each region.
2. Each vehicle executes a single-vehicle DTRP policy in its own subregion.

Using as single-vehicle policy the routing policy described above, the average system time $\bar{T}$ in heavy-load satisfies

$$\bar{T} \leq \gamma(p) \frac{A}{v^2} \frac{\lambda}{n^2 (1 - \rho)^2} + \bar{s}, \quad (\rho \rightarrow 1^-).$$

Hence, by comparing this result with the corresponding lower bound, one concludes that a simple partitioning strategy leads to a multi-vehicle routing policy whose performance is arbitrarily close to the optimal one in heavy load.

Mode of Implementation

The scalability of the control policies to large groups of vehicles often requires a distributed implementation of multi-vehicle routing strategies. For the DTRP, a distributed implementation can be obtained by devising *decentralized*

algorithms for environment partitioning. In the solution proposed in Pavone (2010), power diagrams are the key geometric concept to obtain, in a decentralized fashion, partitions suitable for both the light-load case (requiring, as seen before, a Median Voronoi Tessellation) and the heavy-load case (requiring an equal-area partition). The power diagram of $\mathcal{Q}$ is defined as

$$V_i = \left\{ q \in \mathcal{Q} \mid \|q - p_i\|^2 - w_i \leq \|q - p_j\|^2 - w_j, \right. \\ \left. \forall j \neq i, j \in \{1, \dots, n\} \right\},$$

where $(p_i, w_i) \in \mathcal{Q} \times \mathbb{R}$ are a set of “power points” and V_i is the subregion associated with the i -th power point. Note that power diagrams are a generalization of Voronoi diagrams: when all weights are equal, the power diagram and the Voronoi diagram are identical. The basic idea, then, is to associate to each vehicle i a *virtual* power point, which is an artificial (or logical) variable whose value is locally controlled by the i -th vehicle. The cell V_i becomes the region of dominance for vehicle i , and each vehicle updates its own power point according to a *decentralized* gradient-descent law with respect to a coverage function (► [Optimal Deployment and Spatial Coverage](#)), until the desired partition is achieved. The reader is referred to Pavone (2010) for more details.

Extensions and Discussion

By integrating additional ideas from dynamics, teaming, and distributed algorithms, the spatial queueing theory approach has been recently applied to scenarios with complex models for the tasks such as time constraints, service priorities, translating tasks, and adversarial generation; has been extended to address aspects concerning robotic implementation such as complex vehicle dynamics, limited sensing range, and team forming; and has even been tailored to integrate humans in the design space; see Bullo et al. (2011) and references therein. Despite the significant modeling differences, the “workflow” is essentially the same as in

the DTRP: a queueing model that captures the salient features of the problem at hand, characterization of the fundamental limitations of performance, and design of algorithms with provable performance bounds. The last step, as for the DTRP, often involves lifting a single-vehicle policy to a multi-vehicle policy through the strategy of environment partitioning. Within this context, a number of partitioning schemes and corresponding *decentralized* partitioning algorithms relevant to a large variety of DVR problems are discussed in Pavone et al. (2009).

This workflow efficiently and transparently *decouples* the three decision-making problems mentioned in the Introduction Section, i.e., “task allocation,” “service scheduling,” and “loitering paths.” In fact, task allocation is addressed via the strategy of environment partitioning, service scheduling is addressed by applying a single-vehicle routing policy within the individual regions of dominance, and the loitering paths resolve in placing the vehicles at or around specific points within the dominance regions (e.g., the median). Note, however, that in some important cases, e.g., DVR problems where goods have to be transported from a pickup location to a delivery location or where vehicles are differentially constrained and operate in a “congested” workspace, multi-vehicle policies that rely on static partitions perform poorly or are not even feasible (Pavone et al. 2009), and task allocation and service scheduling need to be addressed as tightly coupled.

Through spatial queueing theory one is usually able to characterize the performance of multi-vehicle routing policies in asymptotic regimes. To ensure “satisfactory” performance under general operation conditions, a common strategy is to consider heuristic modifications to a baseline asymptotically efficient routing policy in such a way that, on the one hand, asymptotic performance is preserved, and, on the other hand, light- and heavy-load performances are “smoothly” and efficiently blended in the intermediate load case. The interested reader can find more information in Bullo et al. (2011).

Summary and Future Directions

The three main approaches available to tackle DVR problems are (i) heuristic algorithms, (ii) competitive analysis, and (iii) spatial queueing theory. Broadly speaking, the competitive analysis approach is well suited when worst-case guarantees are sought, e.g., because there is not enough statistical information about the problem at hand. Spatial queueing theory represents a powerful alternative in cases where it is possible to leverage statistical information and one seeks average-case guarantees. Finally, for some problems the complexity of the model makes an analytical treatment very difficult, in which case the only option is to resort to an heuristic approach (possibly relying on insights derived by applying competitive analysis and/or spatial queueing theory to a simplified version of the problem).

Future directions include the extension of the three aforementioned approaches to increasingly complex problem setups, for example, higher-fidelity vehicle dynamics and environments and sophisticated sensing and communication constraints, novel applications (e.g., search and rescue missions, map maintenance, and pursuit-evasion), and inclusion of game-theoretical tools to address adversarial scenarios. Specifically, for the spatial queueing theory approach, key future directions include the problem of addressing optimality of performance in intermediate regimes (current optimality results are only available either in the light or heavy-load regimes), online estimation of the statistical parameters (e.g., spatial distribution of the tasks), and formulations that take into account second-order moments and large-deviation probabilities.

Nash Equilibrium Seeking over Networks

Lacra Pavel

Engineering, University of Toronto, Toronto,
ON, Canada

Abstract

In the classical approach of Nash equilibrium seeking, players make decisions such that their own cost is minimized assuming that they observe all others' actions/decisions. This requirement can be impractical in distributed multi-agent systems and networks. When extending Nash equilibrium seeking to networks, one has to consider the issue of incomplete information on the opponents' decisions and how handle it via networked information exchange. This entry provides an overview of algorithms/dynamics that can accomplish this. We focus on the interplay between game and communication graph properties in achieving convergence and on system theoretic connections.

Multi-agent systems

Introduction

Many examples of decision-making problems in multi-agent networks can be modeled as games on/over networks (Marden and Shamma 2013; Pavel 2012; Stankovic et al. 2012; Bauso 2016; Yin et al. 2011). The agents can be the network nodes, the users in a communication network, or the robots in a coverage control problem. They are modeled as players in a game, each with their own goal to pursue (e.g., maximum transmission bandwidth or minimum interference). Agents are taking actions/decisions so as to maximize their own individual payoff/utility or equivalently, to minimize their cost, but their payoff/cost depends on (is coupled to) what others are doing. The relevant game equilibrium solution is the Nash equilibrium (Nash 1950), a state where each agent's decision is individually optimal with respect to the others' decisions/strategies. This Nash equilibrium (NE) state should be achieved in an online and autonomous manner, even though agents' own decision-making is coupled to the others' decisions. The dynamic decision-making processes by which players attempt to reach a NE are called Nash equilibrium seeking algorithms/dynamics, part of the larger topic of

learning in games (Fudenberg and Levine 1998). In the classical approach, each player observes all others' actions/decisions. In recent years, there have been sustained efforts to generalize the classical setting of Nash equilibrium seeking and consider the issue of incomplete information on the opponents' decisions and how to deal with it via networked information exchange (Gharesifard and Cortes 2013; Wang et al. 2013; Li and Marden 2013; Swenson et al. 2015; Koshal et al. 2016; Salehisadaghiani and Pavel 2016).

This effort is motivated by the proliferation of engineering networked applications requiring distributed protocols that operate under local information (e.g., vehicle-to-vehicle, peer-to-peer, ad hoc, smart-grid networks), where a player is inherently limited to being observable to and communicate with a few other players. In this entry, we discuss approaches proposed for Nash equilibrium over networks, focused on continuous-kernel games and pointing out some of the challenges and future directions.

Motivating Examples

As a motivating example, consider distributed routing over a network modeled as a noncooperative congestion game. A set of N drivers select their route by relying on local information obtained from their neighbors, such as in vehicular ad hoc networks via community-based navigation, e.g., Waze. Drivers/agents select a route so that they minimize their own driving time, but each does it based on communicating with drivers in their own neighborhood in order to gather information about the other drivers and the state of the traffic. Another example is opportunistic spectrum access for cognitive radio networks, where unlike traditional wireless networks, users adaptively adjust their operating parameters based on interactions with the environment and other users in the network (Cheng et al. 2014; Swenson et al. 2015). These examples are noncooperative in the way actions are taken (each agent takes an action to minimize its own individual cost function), but collaborative, in the sense that agents agree to share some information with neighbors to compensate for the lack of global information on others' decisions. In both

cases, the goal is for agents to reach a Nash equilibrium.

NE Characterization and Classical NE Seeking

We start by giving a formal characterization of a Nash equilibrium (NE) and classical NE seeking schemes. Consider a set $\mathcal{N} = \{1, \dots, N\}$ of N players (agents) involved in a game. Each player $i \in \mathcal{N}$ controls its action/decision $x_i \in \Omega_i$, where $\Omega_i \subseteq \mathbb{R}^{n_i}$ and aims to minimize its own cost function $J_i(x_i, x_{-i})$, $J_i : \Omega \rightarrow \mathbb{R}$, which depends on possibly all other players' actions, x_{-i} . By $x_{-i} \in \Omega_{-i}$ we denote the $(N-1)$ -tuple of all agents' actions/decisions except agent i 's. Let $x = (x_i, x_{-i}) \in \Omega$, or in stacked notation, $x = [x_1^T \dots x_N^T]^T \in \Omega$, denote the profile of all agents' actions, where $\Omega = \prod_{i \in \mathcal{N}} \Omega_i \subseteq \mathbb{R}^n$, $n = \sum_{i \in \mathcal{N}} n_i$. We denote this game by $\mathcal{G}(\mathcal{N}, \Omega_i, J_i)$.

Definition 1 Given a game $\mathcal{G}(\mathcal{N}, \Omega_i, J_i)$, an action profile $x^* = (x_i^*, x_{-i}^*) \in \Omega$ is a Nash equilibrium (NE) of the game if

$$(\forall i \in \mathcal{N})(\forall x_i \in \Omega_i) \quad J_i(x_i^*, x_{-i}^*) \leq J_i(x_i, x_{-i}^*)$$

At a Nash equilibrium, no agent has any incentive to unilaterally change its decision; hence, a NE is a self-enforceable solution. Existence of a Nash equilibrium is guaranteed based on Kakutani's fixed-point theorem, when Ω_i is non-empty, compact, and convex and $J_i(x_i, x_{-i})$ is jointly continuous and convex in x_i for every given x_{-i} , cf. Theorem 4.4 in Başar and Olsder (1999). For continuously differentiable costs, a NE $x^* \in \Omega$ is characterized as a solution of the following variational inequality:

$$(x - x^*)^T F(x^*) \geq 0 \quad \forall x \in \Omega \quad (1)$$

where $F(x) := (\nabla_{x_i} J_i(x_i, x_{-i}))_{i \in \mathcal{N}}$ denotes the stacked vector with all partial gradients $\nabla_{x_i} J_i(x_i, x_{-i})$, of J_i with respect to x_i , cf. Proposition 1.4.2 (Facchinei and Pang 2007). Agents have different cost functions so F :

$\Omega \rightarrow \mathbb{R}^n$ is not a true gradient, and it is called the *pseudo-gradient (game) map*. Alternatively, $x^* = (x_i^*, x_{-i}^*)$ is a (fixed-point) solution to the set of equations, cf. Proposition 1.5.8 (Facchinei and Pang 2007):

$$x_i^* = P_{\Omega_i}(x_i^* - \alpha_i \nabla_{x_i} J_i(x_i^*, x_{-i}^*)), \forall i \in \mathcal{N}, \quad (2)$$

where P_{Ω_i} denotes the Euclidean projection onto Ω_i .

The inherent coupling between the agents' decisions, (2), introduces challenges: when optimizing for their own reward, agents need to know the others' decisions. In a repeated game, players use previous game iterations to gather information about other agents or the game and adjust their decisions/actions. The hope is for agents to come up with a solution of the game, hence find by themselves or seek the unknown NE x^* . The process that describes how an agent i updates its decision in time gives the agent i 's learning/seeking dynamics, denoted by Σ_i . Typical classes of dynamics are best-response play (fictitious-play), projected-gradient (better-response) play, and reinforcement-learning (payoff-based learning) (Fudenberg and Levine 1998; Frihauf et al. 2012), each with different information requirements and convergence guarantees. In this entry, we consider the first two classes. In the classical approach to Nash equilibrium seeking via best-response or gradient (better-response) play, agents observe all other players' actions as in Li and Başar (1987), Shamma and Arslan (2005), Facchinei and Pang (2007), and Scutari et al. (2014). For example, based on (2), in a discrete-time projected gradient-play, at iteration k each player i updates its action as in

$$\Sigma_i : x_i(k+1) = P_{\Omega_i}(x_i(k) - \alpha_{k,i} \nabla_{x_i} J_i(x_i(k), x_{-i}(k))), \quad (3)$$

where $\alpha_{k,i} > 0$ is a step-size. This can be modeled in continuous-time as

$$\Sigma_i : \dot{x}_i = \Pi_{\Omega_i}(x_i, -\nabla_{x_i} J_i(x_i, x_{-i})), \quad (4)$$

where $\dot{x}_i$ denotes the time derivative of x_i and $\Pi_{\Omega_i}(x_i, v) = \lim_{\delta \rightarrow 0} \frac{P_{\Omega_i}(x_i + \delta v) - x_i}{\delta}$ denotes the orthogonal projection of a vector v onto the tangent cone of Ω_i at x_i , hence a projected dynamical system (Nagurney and Zhang 1996). The overall interconnected dynamical system obtained from all agents' dynamics Σ_i is denoted by $\Sigma = (\Sigma_i, \Sigma_{-i})$ and is given in stacked notation as

$$\Sigma : \dot{x} = \Pi_{\Omega}(x, -F(x)), \quad (5)$$

Thus, the overall projected-gradient dynamics is a feedback interconnection between a bank of integrators and a static map involving the pseudo-gradient map F . Either the discrete-time scheme (3) with diminishing/constant step-sizes (Facchinei and Pang 2007) or the continuous-time one (4) (Arrow et al. 1951) (Flåm and Morgan 2004) converge globally to the NE when F is Lipschitz and strictly/strongly monotone.

Assumption 1 (i) F is strictly monotone: $(x - y)^T (F(x) - F(y)) > 0, \forall x, y \in \Omega, x \neq y$.
(ii) F is μ -strongly monotone: $(x - y)^T (F(x) - F(y)) \geq \mu \|x - y\|^2, \forall x, y \in \Omega, \mu > 0$.

Note that in (3) or (4), the knowledge required by each player i at every time is its own cost J_i and all the others' actions x_{-i} , i.e., *perfect-decision information*. This is also the case when this perfect-decision information is obtained via broadcast from a *central control node or coordinator*, (Grammatico 2017; Paccagnan et al. 2019). In this entry, we discuss NE seeking over networks under *partial-decision information* setting, where agents exchange information only locally with their neighbors over a network of arbitrary topology, in a *center-free (distributed)* manner.

NE Seeking over Networks

We next introduce the *partial-decision information* setting over networks. Consider that each player i does not know the actions of all other players x_{-i} (even though this is needed in order

to make a decision) and there is no central node to disseminate this information. To compensate for the lack of global information, players communicate locally with their neighbors. Consider that the information sharing between players is described by a communication graph $G_c = (\mathcal{N}, E)$ of arbitrary topology, undirected and connected, where E denotes the edge set. Let $\mathcal{N}_i = \{j \in \mathcal{N} | (j, i) \in E\}$ denote the set of neighbors of agent i in G_c . Each player i uses local feedback from its neighbors to learn the decisions/actions of all others, i.e., to estimate x_{-i} . For example, in Fig. 1, the feedback signal s_j from neighbor $j \in \mathcal{N}_i$ can be its decision x_j and/or its signaling/state variables. Thus, assume that player i maintains its own estimate $\mathbf{x}_{-i}^i$ of x_{-i} and updates its action based on this estimate. Hence, its state $\mathbf{x}^i = (x_i, \mathbf{x}_{-i}^i)$ encompasses its own decision/action and its estimate of the others' decisions.

Unlike the classical setting of perfect information, in a partial-decision information setting for game-theoretic decision-making, each agent runs two dynamical processes: one for the estimation of the others' decisions/actions and another one for the update of its own action/decision. These two processes depend on one another and depend also on what the other players are doing. This interdependence and dynamic coupling makes it difficult to analyze their convergence.

Nash Equilibrium Seeking over Networks, Fig. 1 NE seeking with partial information over network G_c

Two Time-Scale Separation or Diminishing Step-Sizes

The simplest way to handle the two dynamical processes (decision estimation and action update) is to decouple them via two time-scale separation, either via diminishing step-sizes or via high-gains. In a discrete-time algorithm proposed by Salehisadaghiani and Pavel (2016), the estimates are updated via an asynchronous gossip-based iteration, and the actions are updated via projected-gradient using these estimates. The algorithm generalizes the aggregative game algorithm of Koshal et al. (2016) to generally coupled games. At each iteration k , one randomly selected player i_k communicates with a neighbor $j_k \in \mathcal{N}_{i_k}$; they average their estimates and update their actions as in

$$\begin{aligned} \Sigma_i : \mathbf{x}_{-i}^i(k) &= \frac{\mathbf{x}_{-i}^i(k) + \mathbf{x}_{-i}^j(k)}{2}, \\ &\forall i, j \in \{i_k, j_k\} \\ x_i(k+1) &= P_{\Omega_i} \left(x_i(k) - \alpha_{k,i} \nabla_i J_{x_i}(x_i(k), \right. \\ &\quad \left. \mathbf{x}_{-i}^i(k) \right) \end{aligned} \quad (6)$$

with $\mathbf{x}_i^i(k) = x_i(k)$, where $\alpha_{k,i}$ are diminishing step-sizes, such that $\sum_{k=1}^{\infty} \alpha_{k,i}^2 < \infty$, $\sum_{k=1}^{\infty} \alpha_{k,i} = \infty$. Under such diminishing step-sizes, the algorithm behaves as if on a two-time scale, with all estimates converging quickly to consensus, which in turn allows to show that players' actions converge almost surely to the NE of the game (cf. Theorem 2 in Salehisadaghiani and Pavel 2016 or Proposition 3 in Koshal et al. 2016). However, with constant step-sizes, gossip-based projected-gradient algorithms converge only to a neighborhood of NE.

In a continuous-time version, each individual player has dynamics Σ_i given as

$$\Sigma_i : \begin{bmatrix} \dot{x}_i \\ \epsilon \dot{\mathbf{x}}_{-i}^i \end{bmatrix} = \begin{bmatrix} \Pi_{\Omega_i} \left(x_i, -\nabla_{x_i} J_i(x_i, \mathbf{x}_{-i}^i) \right) \\ - \sum_{j \in \mathcal{N}_i} (\mathbf{x}_{-i}^i - \mathbf{x}_{-i}^j) \end{bmatrix} \quad (7)$$

where $\epsilon > 0$ is a small parameter. For games with unconstrained action sets, this is in the standard form of a singularly perturbed system (Khalil 2002), where the estimate dynamics is the fast subsystem (with high-gain $\frac{1}{\epsilon}$) and the projected-gradient dynamics is the slow subsystem, respectively. The quasi-steady state of the fast subsystem is on the estimate-consensus subspace, and, for small enough ϵ , convergence to the NE can be shown when the pseudo-gradient is strictly/strongly monotone (see Theorem 3 in Gadjov and Pavel 2019 or Theorem 2 in Ye and Hu 2017). Thus, continuous-time dynamics or discrete-time schemes that simply combine consensus dynamics with projected-gradient operate as if on a two-times scale. In order to achieve exact convergence, it is critical that the estimate disagreement is quickly decaying (requiring diminishing step-sizes or small ϵ), while when using constant step-sizes, these algorithms can only guarantee convergence to a neighborhood of the NE.

Single-Time-Scale Dynamics

Under time-scale separation of the two dynamical processes (decision estimation and action update), convergence is easier to establish, but such schemes/dynamics have generally slow convergence. Next, we discuss the more difficult case when the two processes operate on a single-time scale, i.e., when agents estimate the others' decisions and simultaneously update their own action. This amounts to agents having to track a moving target (which affects their own action and also depends on it) while also acting. Essentially players perform simultaneous player-by-player optimization and consensus of estimates. One such dynamics proposed by Gadjov and Pavel (2019) achieves convergence on a single-time scale by employing a consensus correction term on the action update. In this case, each player dynamics Σ_i is given as

$$\Sigma_i : \begin{bmatrix} \dot{x}_i \\ \dot{\mathbf{x}}_{-i}^i \end{bmatrix} = \begin{bmatrix} \Pi_{\Omega_i} \left(x_i, -\nabla_{x_i} J_i(x_i, \mathbf{x}_{-i}^i) - \sum_{j \in \mathcal{N}_i} (x_i - \mathbf{x}_i^j) \right) \\ - \sum_{j \in \mathcal{N}_i} (\mathbf{x}_{-i}^i - \mathbf{x}_{-i}^j) \end{bmatrix} \quad (8)$$

N

This is a projected-gradient with consensus correction based on local feedback. The correction term is inspired by the multi-agent agreement/consensus problem (Bürger and De Persis 2015) and arises naturally from a passivity-based design. With $\mathbf{x}^i = (x_i, \mathbf{x}_{-i}^i)$ and $\mathbf{x} = (\mathbf{x}^i)_{i \in \mathcal{N}}$, the overall interconnected dynamics $\Sigma = (\Sigma_i, \Sigma_{-i})$ are written in stacked form on the augmented space of decisions and estimates as

$$\Sigma : \quad \dot{\mathbf{x}} = \mathcal{R}^T \Pi_{\Omega}(\mathcal{R}\mathbf{x}, -\mathbf{F}(\mathbf{x}) - \mathcal{R}\mathbf{L}\mathbf{x}) - \mathcal{S}^T \mathbf{S}\mathbf{L}\mathbf{x}$$

where $\mathbf{F}(\mathbf{x}) := (\nabla_{x_i} J_i(\mathbf{x}^i))_{i \in \mathcal{V}} : \Omega^N \rightarrow \mathbb{R}^n$ is the *extended* pseudo-gradient of the game, $\mathbf{L} = L \otimes \mathbf{I}_n$, L is the Laplacian of G_c , and $\mathcal{R}, \mathcal{S}$ are matrices used to select actions and estimates from $\mathbf{x}$, e.g., $x = \mathcal{R}\mathbf{x}$. The overall Σ is represented as the feedback interconnected system in Fig. 2,

where the correction term appears as an extra feedback loop via the Laplacian of G_c .

Convergence to the NE can be shown by exploiting incremental passivity properties (Pavlov and Marconi 2008) and the fact that the Laplacian excess passivity can be used to balance the other game-dependent terms. Under monotonicity (passivity) of the extended pseudo-gradient $\mathbf{F}$, single-time-scale convergence to the NE holds over any connected communication graph G_c , cf. Theorem 4 in Gadjov and Pavel (2019). When monotonicity of $\mathbf{F}$ does not hold, single-time-scale convergence can be guaranteed over *any sufficiently connected* graph G_c , under just Lipschitz continuity of $\mathbf{F}$. The idea is to decompose the augmented space into the consensus subspace, where monotonicity holds by Assumption 1, and its orthogonal complement. Then, one can balance the shortage

Nash Equilibrium Seeking over Networks, Fig. 2
Block diagram of $\Sigma = (\Sigma_i, \Sigma_{-i})$

of passivity of $\mathbf{F}$ off the consensus subspace by excess passivity (strong monotonicity) of L on its complement, cf. Theorem 5 in Gadjov and Pavel (2019). Thus, a passivity-based approach highlights the trade-off between game properties and communication graph properties in Nash equilibrium seeking over networks. A discrete-time variant developed by Salehisadaghiani et al. (2019), based on an ADMM approach, has a similar correction term on the action update. Such a term seems to be critical in order to guarantee exact convergence on a single-time scale under constant step-sizes.

Comparison to Distributed Optimization and Multi-agent Agreement

Distributed NE seeking over networks is related to distributed optimization, a problem extensively studied over the past decade, e.g., Nedic and Ozdaglar (2010). However, there are differences between the two settings. In distributed optimization, optimality is in terms of an aggregate convex objective function; each agent optimizes a part of this aggregate objective (cooperate) and has complete authority over its full argument (decoupled problems). Because of this and the summable cost structure, even when the cost is not separable, one can extend the problem to an augmented space of estimates, where it becomes convex and separable, thus easily leading to distributed algorithms. In contrast, in a game setting, there are multiple self-interested decision-makers, each with their own individual objective function which is partially convex only. Furthermore, each objective depends on the others'

decisions (coupled problems), but each agent has authority only over its own actions. This translates into challenges when developing distributed Nash equilibrium seeking algorithms over networks. The major technical difficulty is due to the fact that one cannot guarantee the preservation of pseudo-gradient monotonicity when extended to the augmented space of actions and estimates. As a result, discrete-time distributed convergent schemes with fixed step-sizes (or single-time-scale continuous ones) are harder to develop than their optimization counterparts.

On the other hand, the design of NE seeking schemes over networks is consistent with standard multi-agent consensus design, e.g., Olfati-Saber et al. (2007), except that here consensus is on the decision estimates and agents' dynamics are not integrators or decoupled identical LTI MIMO systems as in typical consensus literature. Rather, the agent dynamics are nonlinear and heterogeneous (e.g., projected-gradient dynamics) similar to multi-agent agreement for general nonlinear systems (Bürger and De Persis 2015). However, unlike (Bürger and De Persis 2015), in a game agents do not have individually passive dynamics, but rather, only partially incrementally passive dynamics, which are coupled to the other players' dynamics. As such, results from the multi-agent agreement literature cannot be directly used. Rather, the analysis has to rely on the incremental passivity (monotonicity) properties of the pseudo-gradient and of the overall system of all agents' interconnected dynamics (Pavel 2019b).

Summary and Future Directions

Nash equilibrium seeking over networks is a recent research direction with many open problems. There is currently a flurry of activity in this area. Recent efforts are focused on how to accelerate convergence (Tatarenko et al. 2018), how to generalize the setting to games with coupled constraints for generalized Nash equilibrium (GNE) seeking (Liang et al. 2017; Yi and Pavel 2019a; Pavel 2019a), how to relax game or communication graph properties

(Yi and Pavel 2019b; Ye and Hu 2018), or how to extend Nash equilibrium seeking to dynamical processes and networks (De Persis and Monshizadeh 2019; Romano and Pavel 2019; De Persis and Grammatico 2018). As of now, there is no method yet that can achieve distributed single-time-scale convergence in (G)NE seeking over networks under partial-decision information for (not strictly/strongly) monotone games. Operator-theoretic splitting methods seem to be particularly useful as they provide elegant, concise convergence proofs (Bauschke and Combettes 2011), (Belgioioso and Grammatico 2018), but distributing them proves to be challenging. Also open is how to develop efficient algorithms/dynamics that exploit the structure of the agents' strategic interaction (e.g., in aggregative games, or at the other end of the spectrum, in games with sparse interference graph), how to deal with delayed/asynchronous information and improve agents' privacy, or how to design incentives against cheating so that agents truthfully share some information.

Network Games

R. Srikant

Department of Electrical and Computer Engineering and the Coordinated Science Lab, University of Illinois at Urbana-Champaign, Champaign, IL, USA

Abstract

Game theory plays a central role in studying systems with a number of interacting players competing for a common resource. A communication network serves as a prototypical example of such a system, where the common resource is the network, consisting of nodes and links with limited capacities, and the players are the computers, web servers, and other end hosts who want to transfer information over the shared network. In this entry, we present several examples of game-theoretic interaction in communication networks and a simple mathematical model to study one such instance, namely, resource allocation in the Internet.

Keywords

Congestion games · Network economics · Price-taking users · Routing games · Strategic users

Introduction

A communication network can be viewed as a collection of resources shared by a set of competing users. If the network were totally unregulated,

then each user would attempt to grab as many resources in the network as possible, resulting in poor network performance, a situation commonly referred to as the *tragedy of the commons* (Hardin 1968). In reality, there is a carefully designed set of network protocols and pricing mechanisms which provide incentives to users to act in a socially responsible manner. Since game theory is the mathematical discipline which studies the interactions between selfish users, it is a natural tool to use to design these network control mechanisms. We now provide a few examples of network problems which naturally lend themselves to game-theoretic analysis. Later, we will elaborate on the game-theoretic formulation of one of these examples.

- *Resource Allocation:* A network such as the Internet is a collection of links, where each link has a limited data-carrying capacity, usually measured in bits per second. The Internet is shared by billions of users, and the actions of these users have to be regulated so that they share the resources in the network in a fair manner. Equivalently, this problem can be viewed as one in which a network designer has to design a collection of protocols so that the users of the network can equitably allocate the available resources among themselves without the intervention of a central authority. Such protocols are built into every computer connected to the Internet today, to allow for seamless operation of the network. The problem of designing such protocols can be posed as a game-theoretic problem in which the players are the network and the traffic sources using the network (Kelly 1997).
 - *Routing Games:* Finding appropriate routes for each user's data traffic is a particular form of resource allocation mentioned above. However, routing has applications beyond communication networks (with the other major application area being transportation networks), so it is useful to discuss routing separately. In communication networks, each user may attempt to find the minimum-delay route for its traffic, with help from the network, to minimize the delay experienced by its packets.
- In a transportation network, each automobile on the road attempts to take the path of least congestion through the network. An active area of research in game theory is one which tries to understand the impact of individual user decisions on the global performance of the network (Roughgarden 2005). An interesting result in this regard is the *Braess paradox* which is an example of a road transportation network in which the addition of a road leads to increased delays when each user selfishly choose a route to minimize its delay. Of course, if routes are chosen to minimize the overall delay experienced in the network, such a paradox will not arise.
- *Peer-to-Peer Applications:* Many studies have indicated that file sharing between users (also known as peers) directly, without using a centralized web site such as YouTube, is a dominant source of traffic in the Internet. For such a peer-to-peer service to work, each peer should not only download files from others but should also be willing to sacrifice some of its resources to upload files to others. Naturally, peers would prefer to only download and not upload to minimize their resource usage. The design of incentive schemes to induce users to both download and upload files is another example of a game-theoretic problem in a network (Qiu and Srikant 2004).
 - *Network Economics:* In addition to end-user interaction, Internet service providers (ISPs) have to interact with each other to allow their customers access to all the web sites in the world. For example, one ISP may have a customer who wants to access a web site connected to another ISP. In this case, the data traffic must cross ISP boundaries, and thus, one ISP has to transport data destined for a customer of another ISP. Thus, ISPs must be willing to contribute resources to satisfy the needs of customers who do not directly pay them. In such a situation, ISPs must have bilateral agreements (commonly known as *peering agreements*) to ensure that the selfish interest of each ISP to minimize its resource usage is aligned with the needs of its customers. Again, game theory is the right tool to study

such inter-ISP interactions (Courcoubetis and Weber 2003).

- *Spectrum Sharing*: Large portions of the radio spectrum are severely underutilized. Typically, portions of the spectrum are assigned to a primary user, but the primary user does not use it most of the time. There has been a surge of interest recently in the concept of *cognitive radio*, whereby radios are cognitive of the presence or absence of the primary user, and when the primary user is absent, another radio can use the spectrum to transmit its data. When there are many users and the available spectrum is split into many channels, it is impossible for users to perfectly coordinate their transmissions to achieve maximum network utilization. In these situations, game-theoretic protocols which take into account the noncooperative behavior of the users can be designed to allow secondary users to access the available channels as efficiently as possible (Saad et al. 2009).

In the next section, we will elaborate on one of the applications above, namely, resource allocation in the Internet, and show how game-theoretic modeling can be used to design fair resource sharing.

Resource Allocation and Game Theory

Consider a network consisting of L links, with link l having capacity c_l . Suppose that there are R users sharing the network, with each user r being characterized by a set of links which connect the user's source to its destination. Since each user uses a fixed route in our model, we will use r to denote both the user and the route used by the user. We use the notation $l \in r$ to denote that link l is a part of route r . Let x_r denote the rate at which user r transmits data. Thus, we have the following natural constraints, which state that the total data rate on any link must be less than or equal to the capacity of the link:

$$\sum_{r:l \in r} x_r \leq c_l, \quad \forall l. \quad (1)$$

Associated with each user is a concave utility function $U_r(x_r)$ which is the utility that user r derives by transmitting data at rate x_r . The network utility maximization problem is to solve

$$\max_{x \geq 0} \sum_r U_r(x_r), \quad (2)$$

subject to the constraint (1). In (2), x denotes the vector $(x_1, x_2, \dots, x_R)$, and $x \geq 0$ means that each component of x must be greater than or equal to zero. Note that the goal of the network in (2) is to maximize the sum of the utilities of the users in the network.

Let p_l be the Lagrange multiplier corresponding to the capacity constraint in (1) for link l . Then the Lagrangian for the problem is given by

$$L(x, p) = \sum_r U_r(x_r) - \sum_l p_l (y_l - c_l), \quad (3)$$

where we have used the notation $y_l := \sum_{r:l \in r} x_r$ to denote the total data rate on link l . If p is known, then the optimal x can be calculated by solving

$$\max_{x \geq 0} L(x, p).$$

Notice that the optimal solution for each x_r can be obtained by solving

$$\max_{x_r \geq 0} U_r(x_r) - q_r x_r, \quad (4)$$

where $q_r = \sum_{l \in r} p_l$. Thus, if the Lagrange multipliers are known, then the network utility maximization can be interpreted as a game in the following manner. Suppose that the network charges each user q_r dollars for every bit transmitted by user r though the network. Then, $q_r x_r$ is the dollar per second spent by the user if x_r is measured in bits per second. Interpreting $U_r(x_r)$ as the dollars per second that the user is willing to pay for transmitting at rate x_r , the optimization problem in (4) is the problem faced by user r which wants to maximize its net utility, i.e., utility minus cost. Thus, the individual optimal

solution for each user is also the solution to the network utility maximization problem. The above game-theoretic interpretation of the network utility maximization problem is somewhat trivial since, given the p_l 's or q_r 's, there is no interaction between the users. Of course, this interpretation relies on the ability of the network to compute p . We next present a scheme to compute p , which couples the users closely and thus allows for a richer game-theoretic interpretation.

Suppose that the network wants to compute p but does not have access to the utility functions of the users. The network asks each user r to bid an amount w_r which is interpreted as the dollars per second that the user is willing to pay. The network then assumes that user r 's utility function is $w_r \log x_r$ and solves the network utility maximization. While this choice of utility function may seem arbitrary, the resulting solution x has a number of attractive properties, including a form of fairness called *proportional fairness*. The proportionally fair resource allocation solution to (4) is given by

$$\frac{w_r}{x_r} = q_r. \quad (5)$$

The network then allocates rate x_r to user r and charges q_r dollars per bit. From (5), the amount charged to user r per second is w_r , thus satisfying the original interpretation of w_r . Knowing that the network charges users in this manner, how might a user choose its bid w_r ? Recall that user r 's goal is to solve (4). Substituting from (5), the problem in (4) can be rewritten as

$$\max_{w_r \geq 0} U_r \left(\frac{w_r}{q_r} \right) - w_r. \quad (6)$$

Thus, the users' problem of selecting w can be viewed as a game, with each user's objective given by (6). Note that q_r is given by (5) and thus depends on all the w_r 's. Depending upon the application, the game can be solved under one of two assumptions:

- *Price-Taking Users:* Under this assumption, users are assumed to take the price q_r as

given, i.e., they do not attempt to infer the impact of their actions on the price. This is a reasonable assumption in a large network such as the Internet, where the impact of a single user on the link prices is negligible, and it is practically impossible for any user to infer the impact of its decisions on the prevailing price of the network resources. When the users are price taking, the socially optimal solution, i.e., the solution to the network utility maximization problem, coincides with the Nash equilibrium of the game. To see this, note that the solution to (6) is given by

$$\frac{1}{q_r} U'_r \left(\frac{w_r}{q_r} \right) - 1 = 0,$$

under the assumption that the utility function is differentiable and the solution is bounded away from zero. Using (5), this equation reduces to

$$U'_r(x_r) = q_r,$$

which maximizes the Lagrangian (3). It is not difficult to see that the complementary slackness equations in the Karush-Kuhn-Tucker conditions are satisfied since the constraints for (2) and the proportionally fair solution are the same. Thus, under the price-taking assumption, the equilibrium of the game solution is the same as the socially optimal solution provided the network computes q_r using the proportionally fair resource allocation formulation.

- *Strategic Users:* In networks where the number of users is small, it may be possible for each user to know the topology of the network, and thus each user may be able to solve for the proportionally fair resource allocation if it has access to other users' bids. In other words, it may be possible to compute a Nash equilibrium by taking into account the impact of the w_r 's on the q_r 's. When the users are strategic, the socially optimal solution could be quite different from the Nash equilibrium. The ratio of the network utility under the socially optimal solution to the network utility

under a Nash equilibrium is called the *price of anarchy*.

There is a rich literature associated with both interpretations of the network congestion game. In the case of price-taking users, much of the emphasis in the literature has been on designing distributed algorithms to achieve the socially optimal solution (Shakkottai and Srikant 2007). In the case of strategic users, the focus has been on characterizing the price of anarchy (Johari and Tsitsiklis 2004; Yang and Hajek 2007).

Summary and Future Directions

We have presented a number of applications which involve the interactions of selfish users over a network. For the resource allocation application, we have also described how simple mathematical models can be used to provide incentives for users to act in a socially optimal manner. In particular, we have shown that, under the reasonable price-taking assumption and an appropriate computation of link prices, selfish users automatically maximize network utility. In the case where the users are strategic, the goal is to characterize the price of anarchy.

Moving forward, two areas which require considerable further research are the following: (i) inter-ISP routing and (ii) spectrum sharing. The Internet is a fairly reliably network, and any unreliability often arises due to routing issues among ISPs. As mentioned in the introduction, peering arrangements between ISPs are necessary to make sure that ISPs carry each others' traffic and are appropriately compensated for it, either through reciprocal traffic-carrying agreements or actual monetary transfer. Thus, the policy that an ISP uses to route traffic may be governed by these peering agreements. The more complicated these policies are, the more chances there are for routing misconfigurations that lead to service interruptions. This interplay between policies and technology in the form of routing algorithms is an interesting topic for further study.

Cognitive radios and spectrum sharing are expected to be significant technological components of future wireless networks. Designing algorithms for selfish radios to share the available spectrum while respecting the rights of the primary user of the spectrum is a challenge that requires considerable further attention. This area of research requires one to combine sensing technologies to sense the presence of other users with game-theoretic models to ensure fair channel access to the secondary users, subject to the constraint that the primary user should not be affected by the presence of the secondary users.

Networked Control Systems: Architecture and Stability Issues

Linda Bushnell¹ and Hong Ye²

¹Department of Electrical and Computer Engineering, University of Washington, Seattle, WA, USA

²The Mathworks, Inc., Natick, MA, USA

Abstract

When shared, band-limited, real-time communication networks are employed in a control system to exchange information between spatially distributed components, such as controllers, actuators, and sensors, it is categorized as a networked control system (NCS). The primary advantages of a NCS are reduced complexity and wiring, reduced design and implementation cost, ease of system maintenance and modification, and efficient data sharing. In addition, this unique architecture creates a way to connect the cyberspace to the physical space for remote operation of systems. The NCS architecture allows for performing more complex tasks but also requires taking the network effects into account when designing control laws and stability conditions. In this entry, we review significant results on the architecture and stability analysis of a NCS. The results presented address communication network-induced challenges such as time delays, scheduling, and information packet dropouts.

Introduction

From the washing machine, air conditioner, and microwave oven to the telephone, stereo, and automobile, embedded computers are present in

the modern home. In a factory environment, there are thousands of networked smart sensors and actuators with embedded processors, working to complete a coordinated task. The trend in manufacturing plants, homes, buildings, aircraft, and automobiles is toward distributed networking. This trend can be inferred from many proposed or emerging network standards, such as controller area network (CAN) for automotive and industrial automation, BACnet for building automation, PROFIBUS and WorldFIP fieldbus for process control, and IEEE 802.11 and Bluetooth wireless standards for applications such as mobile sensor networks, HVAC systems, and unmanned aerial vehicles.

The traditional dedicated point-to-point wired connection in control systems has been successfully implemented in industry for decades. With the advance of communication network and hardware technologies, it is common to integrate the communication network into the control system to replace the dedicated point-to-point connection to achieve reduced weight and power, lower cost, simpler installation and maintenance, and higher reliability, to name a few advantages. For example, a typical new automobile has two controller area networks (CANs): a high-speed one in front of the firewall for the engine, transmission, and traction control and a low-speed one for locks, windows, and other devices (Johansson et al. 2005).

The conventional definition of a networked control system (NCS) is as follows: When a feedback control system is closed via a communication channel, which may be shared with other nodes outside the control system, then the control system is called a NCS. A NCS can also be described as a feedback control system where the control loops are closed through a real-time communication network.

Architecture of Networked Control Systems

The architecture of a NCS consists of a band-limited, digital communication network

physically and electronically integrated with a spatially distributed control system, operated on a given plant. Digital information, such as controller signals, actuator signals, sensor signals, and operator input, is transmitted via the network. The components connected by the network include all nodes of the control system, such as the supervisory (or “network owner”) computer, controller software and hardware, actuators, and sensors. In this structure, the feedback control system’s loops are closed over the shared communication network.

The communication network can be wired or wireless and may be shared with other unrelated nodes outside the control system. As illustrated in Fig. 1, the shared communication channel, which multiplexes signals from the sensors to the controllers and/or from the controllers to the actuators, serves many other uses besides control. Each of the system components directly connected to the network via a network interface is denoted a physical node. Besides the network interface, the sensors and actuator nodes are typically smart nodes with embedded microprocessors. Sometimes, the controller is colocated with the smart actuator. Several key issues make networked control systems distinct from traditional control systems (Hespanha et al. 2007; Yang 2006).

Band-Limited Channels

Bandwidth limitation of the shared communication channel requires that all nodes in the network must share (e.g., time sharing or frequency sharing, etc.) the common network resource without interfering with each other.

Sampling and Delays

In a NCS, the plant outputs are sampled by the sensors, which can convert continuous-time analog signals to digital signals; perform preprocessing, filtering, and encoding; and package the data signal so that it is ready for transmission. After winning the medium access control and being transmitted over the network, the package containing the sampled data signal arrives at the receiver side, which could be a controller or a smart actuator with a controller collocated with it. The receiver unpacks and decodes the signal. This process is quite different from the traditional periodic sampling in digital control. The overall delay between sampling and the eventual decoding of the transmitted packet at the receiver can be time varying and random due to both the network access delay (i.e., the time it takes for a shared network to accept the data) and the transmission delay (i.e., the time during which data are in transit inside the network). This also depends on the highly variable network

Networked Control Systems: Architecture and Stability Issues, Fig. 1 A general networked control system (NCS) architecture

conditions, such as congestion and channel quality. In some NCSs, the data transmitted are time stamped, which means that the receiver may have an estimate of the delay's duration and could take appropriate corrective action. Given the rapid advance of embedded computation and communication hardware technology today, the transmission delay in many embedded systems can be neglected when compared with the magnitude of network access delay.

Packet Dropouts

It is possible in a NCS that a packet may be lost while it is in transit through the network. The packet that contains important sampling data or control signals may drop occasionally due to transmission errors of the physical network link, message collision, or node failures, to name a few. Overflow in queue or buffer can lead to network congestion and package loss. Thus, the use of queues is not favored by NCSs in general. Packet dropouts also happen if the receiver discards outdated arrivals that have long delays. Most network protocols are equipped with transmission-retry mechanisms, such as TCP, that guarantee the eventual delivery of packets. These protocols, unfortunately, are not appropriate for a NCS since the retransmission of old sensor data or calculated control signals is generally not very useful when new, time-critical data are available. Using selected old data for estimation or prediction is an exception, where old data may be packaged with the new data in one packet. It is advantageous to discard the old, un-transmitted data and transmit a new packet if and when it becomes available. In this way, the controller always receives fresh data for its control calculation, and the actuator always executes the up-to-date command to control the plant.

Modeling Errors, Uncertainties, and Disturbances

In a distributed NCS, modeling errors, uncertainties, and disturbances always exist when using the mathematical model to describe the physical process. These factors may lead to a major impact on the overall system performance and cause

failure in fulfilling the desired objectives. Wang and Hovakimyan (2013) proposed a reference model-based architecture to decouple the design of controller and communication schemes. A reference model is introduced in each subsystem as a bridge to build the connection between the real system and an ideal model, free of uncertainties. The closeness between the real system and the reference model is associated only with plant uncertainties, and the difference between the reference model and the ideal model is only in the communication constraints.

Stability of Networked Control Systems

The stability of a control system is often extremely important and is generally a safety requirement. Examples include the control of rockets, robots, airplanes, automobiles, or ships. Instability in any one of these systems can result in an unimaginable accident and loss of life. The stability of a general dynamical system with no input can be described with the Lyapunov stability criteria, which is stated as follows: A linear system is stable if its impulse response approaches zero as time approaches infinity or if every bounded input produces a bounded output.

When sensors, controllers, and actuators are not colocated and use a shared network to communicate, the feedback loop of a NCS is closed over the network. Network-induced, variable delays and packet dropouts can degrade the performance of a NCS. For example, the NCS may have a longer settling time or bigger overshoot in the step response. Furthermore, the NCS may become unstable when delays and/or packet dropouts exceed a certain range. Designers choosing to use a NCS architecture, however, are motivated not by performance but by cost, maintenance, and reliability gains.

Band-Limited Channels

Inspired by Shannon's results on the maximum bit rate that a communication channel can carry reliably, a significant research effort has been devoted to the problem of determining the

minimum bit rate that is needed to stabilize a system through feedback over a finite capacity channel (Baillieul 1999; Nair and Evans 2000; Tatikonda and Mitter 2004; Wong and Brockett 1999; Baillieul and Antsaklis 2007). This has been solved exactly for linear plants, but only conservative results have been obtained for nonlinear plants. The data-rate theorem that quantifies a fundamental relationship between unstable physical systems and the rate at which information must be processed in order to stably control them was proved independently under a variety of assumptions. Minimum bit rate and quantization becomes especially important for networks designed to carry very small packets with little overhead, because encoding measurements or actuation signals with less bits can save network bandwidth.

Most of the NCS stability results presented here, however, are based on the observation that the channel can transmit a finite number of packets per unit of time (packet rate) and each packet can carry certain number of bits in the data field. The packets on a real-time control network typically are frequent and have small data segments compared to their headers. For example, a CAN II packet with a single 16-bit data sample has fixed 64 bits of overhead associated with identifier, control field, CRC, ACK field, and frame delimiter, resulting in 25% utilization, and this utilization can never exceed 50% (data field length is limited to 64 bits). Thus, the quantization effects imposed by the communication networks are generally ignored.

Network-Induced Delays

A significant number of results have attempted to characterize a maximum upper bound on the sampling or transmission interval for which stability of the NCS can be guaranteed. The upper bound is sometimes called the maximum allowable transfer interval (MATI) (Walsh 2001a). These results implicitly attempt to minimize the packet rate or schedule the traffic of the control network that is needed to stabilize a system through feedback. The general approach is to design the controller using established techniques, considering the network to be

transparent, and then to analyze the effect of the network on closed-loop system performance and stability.

The NCS with a linear time-invariant (LTI) plant/controller pair and one-channel feedback (see Fig. 2) can be modeled by the following continuous-time system, where x includes the states of the plant and the controller, $x(t) = [x_p(t), x_c(t)]^T$:

$$\dot{x} = Ax + B\hat{y}, y = C(x) \quad (1)$$

$$\hat{y}(t) = \begin{cases} \hat{y}_{k-1}, & t \in [t_k, t_k + \tau_k) \\ \hat{y}_k, & t \in [t_k + \tau_k; t_{k+1}) \end{cases} \quad (2)$$

The signal y is a vector of sensor measurements, and $\hat{y}$ is the input to a continuous-time controller collocated with the actuators. Alternatively, $\hat{y}$ can be viewed as the input to the actuators and y as the desired control signal computed by a controller collocated with the sensors. The signal $y(t)$ is sampled at times $\{t_k : k \in N\}$ and the samples $y(k) := y(t_k)$ are sent through the network. But the samples arrive at the destination after a (possibly variable) delay of τ_k , where we assume that the network delays are always smaller than one sampling interval. For periodic sampling and constant delays, a sufficient and necessary condition for exponential stability of the NCS (Eqs. 1 and 2) was derived (Zhang et al. 2001). By using the augmented state space model and based on the stability of nonlinear hybrid systems, they also proved the sufficient condition for stability of the NCS in the time-invariant case.

If we now assume the sampling intervals are constant and the computation and transmission delays are negligible, then the variable network

Networked Control Systems: Architecture and Stability Issues, Fig. 2 A NCS architecture with one-channel feedback (controller collocated with actuator)

access delays serve as the main source of delays in a NCS (Lin et al. 2003, 2005). Using average dwell time results for discrete switched systems, Zhai et al. (2002) provided conditions such that NCS stability is guaranteed. Also, the authors consider robust disturbance attenuation analysis for this class of NCSs.

When the network delay is not constant or when the signal $y(t)$ is sampled in a nonperiodic fashion, the system (1) and (2) is not time invariant and one needs a Lyapunov-based argument to prove its stability. Zhang and Branicky (2001) derived the sufficient condition to ensure the NCS in Fig. 2 is exponentially stable. They also proposed a randomized algorithm to find the largest value of sampling interval for which stability can be guaranteed.

For a model-based NCS with state and output feedback, an explicit model of the plant is used to produce an estimate of the plant state behavior between transmission times (Montestruque and Antsaklis 2004). Sufficient conditions for Lyapunov stability are derived for a model-based NCS when the controller/actuator is updated with the sensor information at nonconstant time intervals. A NCS with transmission times that are driven by a stochastic process with identically independently distributed and Markov-chain-driven transmission times almost sure stability and mean-square sufficient conditions for stability are introduced. Onat et al. (2011) adapted above stability results to model-based predictive NCSs with realistic structure assumptions.

Control Network Scheduler

In general a multi-input/multi-output (MIMO) NCS with two-channel feedback, both the sampled plant output and controller output are transmitted via a network (see Fig. 3). Because of the network, only the reported output $y(t)$ is available to the controller and its prediction processes; similarly, only $\hat{u}(t)$ is available to the actuators on the plant. We label the network-induced error

$$e(t) := [\hat{y}(t), \hat{u}(t)]^T - [y(t), u(t)]^T$$

and the combined state of controller and plant $x(t) = [x_p(t), x_c(t)]^T$. The state of the entire

Networked Control Systems: Architecture and Stability Issues, Fig. 3 A NCS architecture with two-channel feedback

NCS is given by $z(t) = [x(t), e(t)]^T$. Following this general approach, the controller is designed using established techniques without considering the presence of the network.

The behavior of the network-induced error $e(t)$ is mainly determined by the architecture of the NCS and the scheduling strategy. In the special case of one-package transmission, there is only one node transmitting data on the network; therefore, the entire vector $e(t)$ is set to zero at each transmission time. For multiple nodes transmitting measured outputs $y(t)$ and/or computed inputs $u(t)$, the transmission order of the nodes depends on the scheduling strategy chosen for the NCS. In other words, the scheduling strategy decides which components of $e(t)$ are set to zero at the transmission times.

Static and dynamic schedulers (a.k.a. protocols) are two main categories used in a NCS. When the network resource or transmission order are pre-allocated or determined before runtime, it is called a static scheduler, such as round-robin scheduling. A dynamic scheduler determines the network allocation while the system runs. A novel dynamic network scheduler, try-once-discard (TOD), and several variations were introduced for wired and wireless NCSs (Walsh and Ye 2001; Ye et al. 2001). For linear and nonlinear NCSs with the new dynamic and commonly used static schedulers, an analytic proof of global exponential stability of a MIMO NCS was provided (Walsh 2001a; Walsh et al. 2001b). Simulation and experiment results showed that the dynamic schedulers outperform static schedulers

in terms of NCS performance, e.g., a bigger MATI.

Nesic and Teel (2004a, b) generalize the above results by considering a nonlinear NCS with external disturbances and more general class of protocols (or schedulers). They considered a new class of Lyapunov uniformly globally asymptotically stable (UGAS) protocols in a NCS. It is shown that if the controller is designed without taking into account the network, it yields input-to-state stability (ISS) with respect to external disturbances (not necessarily with respect to the network-induced error), and then the same controller will achieve semi-global practical ISS for the NCS when implemented via the network with a Lyapunov UGAS protocol. Moreover, the ISS gain is preserved. The adjustable parameter with respect to which semi-global practical ISS is achieved is the MATI between transmission times. The authors also studied the input–output L_p stability of a NCS for a large class of network scheduling protocols. It is shown that polling, static protocols, and dynamic protocol such as TOD belong to this class. Results in Nesic and Teel (2004a) provide a unifying framework for generating new scheduling protocols that preserve L_p stability properties of the system, if a design parameter is chosen to be sufficiently small. The most general version of these results can also be used to model a NCS with data packet dropouts. The proof technique used is based on the small gain theorem and lends itself to an easy interpretation.

A framework for analyzing the stability of a general nonlinear NCS with disturbances in the setting of L_p stability was provided by Tabbara et al. (2007). Their presentation provides sharper results for both gain and MATI than previously obtainable and details the property of uniformly persistently exciting scheduling protocols. This class of protocols was shown to lead to stability for high enough transmission rates. This was a natural property to demand, especially in the design of wireless scheduling protocols. The property is used directly in a novel proof technique based on the notions of vector comparison and (quasi)-monotone systems. Via simulations, analytical, and numerical comparison, it

is verified that the uniform persistence of excitation property of protocols is, in some sense, the “finest” property that can be extracted from wireless scheduling protocols.

Delays and Packet Dropouts

Packet dropouts can be modeled as either stochastic or deterministic phenomena. For a one-channel feedback NCS, Zhang and Branicky (2001) consider a deterministic dropouts model, with packet dropouts occurring at an asymptotic rate. Stability conditions were studied for a NCS with deterministic and stochastic dropouts (Seiler and Sengupta 2005).

Sometimes, the NCS was characterized as a continuous-time delayed differential equation (DDE) with the time-varying delay $\tau(t)$. One important advantage is that the equations are still valid even when the delays exceed the sampling interval. Researchers successfully used the Lyapunov–Krasovskii (Yue et al. 2004) and the Razumikhin theorems (Yu et al. 2004) to study the stability of a NCS that is modeled as DDEs.

Summary and Future Directions

This article introduced the concept of a networked control system and its general architecture. Several key issues specific to a NCS, such as band-limited channels, network-induced delays, and information packet dropouts, were explained. The stability condition of a NCS with various network effects was discussed with several common modeling techniques.

In terms of future directions, there has been significant effort in analyzing networked control systems with variable sampling rate, but most results investigate the stability for a given worst-case interval between consecutive sampling times, leading to conservative results. An open area of research would be to look at methods that take into account a stochastic characterization for the inter-sampling times. Substantial work has also been devoted to determining the stability of a NCS, as described in this article. Possible open areas of research would be to consider design issues related to the joint stability and

performance of the system. The design and development of controllers for a NCS is also an open area of research. In designing a controller for a NCS, one has to take into account the challenges introduced by the communication network. Only afterward can analysis of the whole system take place.

Abstract

This entry discusses optimal estimation and control for lossy networks. Conditions for stability are provided both for two-link and multiple-link networks. The online adaptation of network resources (controlled communication) is also considered.

Keywords

Automatic control · Communication networks · Controlled communication · Estimation · Networked control systems · Stability

Introduction

Network Control Systems (NCSs) are spatially distributed systems in which the communication between sensors, actuators, and controllers occurs through a shared band-limited digital communication network. In this entry, we consider the problem of estimation and control over such networks.

A significant difference between NCSs and standard digital control is the possibility that data may be lost while in transit through the network. Typically, *packet dropouts* result from transmission errors in physical network links (which is far more common in wireless than in wired networks) or from buffer overflows

due to congestion. Long transmission delays sometimes result in packet reordering, which essentially amounts to a packet dropout if the receiver discards “outdated” arrivals. Reliable transmission protocols, such as TCP, guarantee the eventual delivery of packets. However, these protocols are not appropriate for NCSs since the retransmission of old data is generally not useful. Another important difference between NCSs and standard digital control systems is that, due to the nature of network traffic, delays in the control loop may be time varying and nondeterministic.

In this entry, we concentrate on the problem of control and estimation in the presence of packet losses, leaving other important features of NCSs (such as quantization and random delays) to be addressed in other entries of this encyclopedia. Consequently, we assume that the network can be viewed as a channel that can carry real numbers without distortion, but that some of the messages may be lost. This network model is appropriate when the number of bits in each data packet is sufficiently large so that quantization effects can be ignored, but packet dropouts cannot. For more general channel models, see, for example, Imer and Basar (2005).

This entry also does not address network transmission delays explicitly. In general, network delays have two components: one that is due to the time spent transmitting packets and another due to the time packets wait in buffers waiting to be transmitted. Delays due to packet transmission present little variation and may be modeled as constants. For control design purposes, these delays may be incorporated into the plant model. Delays due to buffering depend on the network traffic and are typically random; they can be analyzed using the techniques developed in Antunes et al. (2012).

Notation and Basic Definitions. Throughout the entry, $\mathbb{R}$ stands for real numbers and $\mathbb{N}$ for nonnegative integers. For a given matrix $A \in \mathbb{R}^{n \times n}$ and vector $x \in \mathbb{R}^n$, $\|x\| := \sqrt{x'x}$ denotes the Euclidean norm of x , and $\lambda(A)$ the set of eigenvalues of A . Random variables are generally denoted in boldface. For a random variable $\mathbf{y}$, $E[\mathbf{y}]$ stands for the expectation of $\mathbf{y}$.

Two-Link Networks

Here, we consider a control/estimation problem when all network effects can be modeled using two erasure channels: one from the sensor to the controller and the other from the controller to the actuator (see Fig. 1).

We restrict our attention to a linear time-invariant (LTI) plant with intermittent observation and control packets:

$$\mathbf{x}_{k+1} = A\mathbf{x}_k + v_k B\mathbf{u}_k + \mathbf{w}_k, \quad (1a)$$

$$\mathbf{y}_k = \theta_k C\mathbf{x}_k + \mathbf{v}_k, \quad (1b)$$

$\forall k \in \mathbb{N}$, $\mathbf{x}_k, \mathbf{w}_k \in \mathbb{R}^n$, $\mathbf{y}_k, \mathbf{v}_k \in \mathbb{R}^p$, where $(\mathbf{x}_0, \mathbf{w}_k, \mathbf{v}_k)$ are mutually independent, zero-mean Gaussian with covariance matrices (P_0, R_w, R_v) , and $\theta_k, v_k \in \{0, 1\}$ are i.i.d. Bernoulli random variables with $\Pr\{\theta_k = 1\} = \bar{\theta}$ and $\Pr\{v_k = 1\} = \bar{v}$. The variable θ_k models the packet loss between sensor and controller, whereas v_k models the packet loss between controller and actuator. When there is a packet drop from controller to actuator, we set the actuator's output to zero. Different strategies, such as holding the control input, could still be modeled using (1) by augmenting of the state vector.

The information available to the controller up to time k is given by the information set:

$$\mathcal{I}_k = \{P_0\} \cup \{\mathbf{y}_\ell, \theta_\ell : \ell \leq k\} \cup \{v_\ell : \ell \leq k-1\}.$$

Here, we make an important assumption that acknowledgment packets from the actuator are always received by the controller so that $v_\ell, \ell \leq k-1$ is available at time k to the remote estimator.

Networked Control Systems: Estimation and Control over Lossy Networks, Fig. 1 Control system with two network links

Optimal Estimation with Remote Computation

The optimal mean-square estimate of $\mathbf{x}_k$, given the information known to the remote estimator at time k , is given by

$$\hat{\mathbf{x}}_{k|k} := E[\mathbf{x}_k | \mathcal{I}_k].$$

This estimate can be computed recursively using the following time-varying Kalman filter (TVKF) (Sinopoli et al. 2004):

$$\hat{\mathbf{x}}_{0|-1} = 0, \quad (2a)$$

$$\hat{\mathbf{x}}_{k|k} = \hat{\mathbf{x}}_{k|k-1} + \theta_k F_k (\mathbf{y}_k - C\hat{\mathbf{x}}_{k|k-1}), \quad (2b)$$

$$\hat{\mathbf{x}}_{k+1|k} = A\hat{\mathbf{x}}_{k|k} + v_k B\mathbf{u}_k, \quad (2c)$$

with the gain matrix F_k calculated recursively as follows

$$F_k = P_k C' (C P_k C' + R_v)^{-1},$$

$$P_{k+1} = A P_k A' + R_w - \theta_k A F_k (C P_k C' + R_v) F_k' A'.$$

Each P_k corresponds to the estimation error covariance matrix

$$P_k = E[(\mathbf{x}_k - \hat{\mathbf{x}}_{k|k-1})(\mathbf{x}_k - \hat{\mathbf{x}}_{k|k-1})'].$$

For this estimator, there exists a critical value θ_c for the dropout rate $\bar{\theta}$, above which the estimation error covariance becomes unbounded:

Theorem 1 (Sinopoli et al. 2004) Assume that $(A, R_w^{1/2})$ is controllable, (A, C) is observable, and A is unstable. Then there exists a critical value $\theta_c \in (0, 1]$ such that

$$E[P_k] \leq M, \forall k \in \mathbb{N} \Leftrightarrow \bar{\theta} \geq \theta_c$$

where M is a positive definite matrix that may depend on P_0 . Furthermore, the critical value θ_c satisfies $\theta_{\min} \leq \theta_c \leq \theta_{\max}$, where the lower bound is given by

$$\theta_{\min} = 1 - \frac{1}{(\max\{|\lambda(A)|\})^2}, \quad (3)$$

and the upper bound is given by the solution to the following (quasi-convex) optimization problem:

$$\theta_{\max} = \min\{\theta \geq 0 : \Psi_{\theta}(Y, Z) > 0, \\ 0 \leq Y \leq I \text{ for some } Y, Z\},$$

where

$$\Psi_{\theta}(Y, Z) = \begin{bmatrix} Y & \sqrt{\theta}(YA + ZC) & \sqrt{1-\theta}YA \\ \sqrt{\theta}(A'Y + C'Z') & Y & 0 \\ \sqrt{1-\theta}A'Y & 0 & Y \end{bmatrix}.$$

Remark 1 In some special cases, the upper bound in (3) is tight in the sense that $\theta_c - \theta_{\min}$. The largest class of systems known for which this occurs is that of *nondegenerate systems* defined in Mo and Sinopoli (2012). Examples of systems in this class include (1) those for which the matrix C is invertible and (2) those with a detectable pair (A, C) and such that the matrix A is diagonalizable with unstable eigenvalues having distinct absolute values.

Optimal Control with Remote Computation

From a control perspective, one may also be interested in finding control sequences $\mathbf{u}^N = \{\mathbf{u}_1, \dots, \mathbf{u}_{N-1}\}$, as functions of the information set $\mathcal{I}_N$, which minimize cost functions of the form

$$J = \lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E} \left[\sum_{k=0}^{N-1} (\mathbf{x}'_k W \mathbf{x}_k + v_k \mathbf{u}'_k U \mathbf{u}_k) | \mathcal{I}_k \right].$$

Theorem 2 (Schenato et al. 2007) Assume that (A, B) and $(A, R_w^{1/2})$ are controllable, (A, C) and $(A, W^{1/2})$ are observable, and A is unstable. Then, finite control costs J are achievable if and only if $\bar{\theta} > \theta_c$ and $\bar{v} > v_c$, where the critical value v_c is given by the (quasi-convex) optimization problem

$$v_c = \min\{v \geq 0 : \Psi_v(Y, Z) > 0, \\ 0 \leq Y \leq I \text{ for some } Y, Z\},$$

where

$$\Psi_v(Y, Z) = \begin{bmatrix} Y & Y & \sqrt{\bar{v}}ZU^{1/2} & \sqrt{\bar{v}}(YA' + ZB') & \sqrt{1-\bar{v}}YA' \\ Y & W^{-1} & 0 & 0 & 0 \\ \sqrt{\bar{v}}U^{1/2}Z' & 0 & I & 0 & 0 \\ \sqrt{\bar{v}}(AY + BZ') & 0 & 0 & Y & 0 \\ \sqrt{1-\bar{v}}AY & 0 & 0 & 0 & Y \end{bmatrix}.$$

Moreover, under the above conditions, the separation principle holds in the sense that the optimal control is given by

$$\mathbf{u}_k = -(B'SB + U)^{-1}B'SA\hat{\mathbf{x}}_{k|k},$$

where $\hat{\mathbf{x}}_{k|k}$ is an optimal state estimate given by (2) and the matrix S is the solution to the modified algebraic Riccati (MARE) equation

$$S = A'SA + W - \bar{v}A'SB(B'SB + U)^{-1}B'SA.$$

Solutions to the MARE may be obtained iteratively when $\bar{v} > v_c$.

Estimation with Local Computation

To reduce the gap between the bounds $\theta_{\min}$ and $\theta_{\max}$ on the critical value of the drop probability in Theorem 1 and to allow for larger probabilities of drop, one may choose to compute state estimates at the sensor and transmit those to the controller/actuator. This scheme is motivated by the growing number of *smart sensors* with

embedded processing units that are capable of local computation. For the LTI plant

$$\begin{aligned}\mathbf{x}_{k+1} &= A\mathbf{x}_k + B\mathbf{u}_k + \mathbf{w}_k, \\ \mathbf{y}_k &= C\mathbf{x}_k + \mathbf{v}_k,\end{aligned}$$

the smart sensor can compute locally an optimal state estimate using a standard stationary Kalman filter and transmits this estimate to the controller. We model packet dropouts as before using the process θ_k and assume that the process θ_k is known to the smart sensor by means of an perfect acknowledgment mechanism. This allows the sensor to know $\mathbf{u}_k$ exactly and to use it in the Kalman filter.

Let $\tilde{\mathbf{x}}_{k|k} = E[\mathbf{x}_k | \mathbf{y}_\ell, \theta_\ell, \ell \leq k]$ denote the local estimates transmitted by the sensor. Using the messages successfully received up to time k , the remote estimator computes the optimal estimate

$$\hat{\mathbf{x}}_{k|k-1} = E[\mathbf{x}_k | \theta_\ell, \tilde{\mathbf{x}}_{\ell|k}, \ell \leq k-1].$$

recursively by

$$\begin{aligned}\hat{\mathbf{x}}_{0|-1} &= 0, \\ \hat{\mathbf{x}}_{k|k} &= (1 - \theta_k)\hat{\mathbf{x}}_{k|k-1} + \theta_k\tilde{\mathbf{x}}_{k|k}, \quad k \in \mathbb{N}, \\ \hat{\mathbf{x}}_{k+1|k} &= A\hat{\mathbf{x}}_{k|k} + B\mathbf{u}_k\end{aligned}$$

Notice that now we are applying the (TVKF) to estimate $\tilde{\mathbf{x}}_k$, which is fully observable. Since $\theta_{\min}$ and $\theta_{\max}$ in Theorem 2 are equal for fully observable processes (Schenato et al. 2007), the local computation scheme grants a minimal critical value θ_c as stated in the theorem below.

Theorem 3 Assume that $(A, R_w^{1/2})$ is controllable, (A, C) is OBSERVABLE, and A is unstable. Then the critical value θ_c is given by $\theta_{\min}$ in (3), i.e.,

$$E[P_k] \leq M, \forall k \in \mathbb{N} \quad \Leftrightarrow \quad \bar{\theta} \geq \theta_{\min}$$

where M is a positive definite matrix that may depend on P_0 .

Drops in the Acknowledgement Packets

When there are drops in the acknowledgment channel from the actuator to the controller, the controller does not always know v_k , and therefore, it might not always have access to the control inputs that are actually applied to the plant. In this case, the posterior state probability becomes a Gaussian mixture distribution with infinitely many components, and the separation principle no longer holds (Schenato et al. 2007). This makes the estimation and control problems computationally more difficult, and, due to the smaller information set, some performance degradation in the control performance should be expected. For this reason, it is generally a good design choice to keep controller and actuator collocated when drops in the acknowledgment channels are significant.

Buffering

As an alternative to the approach described in section “Estimation with Local Computation” to use local computation at a smart sensor to allow for larger probabilities of drop, the designer may also consider the transmission of a sequence of previous measurements $\mathbf{y}_k, \mathbf{y}_{k-1}, \dots, \mathbf{y}_{k-N}$ in each packet. This approach is motivated by the fact that often data packets can carry much more than one vector of measured outputs. When N is reasonably large, one should expect similar estimation/control performances as in the approach described in section “Estimation with Local Computation”, but with a reduced computational effort at the sensor.

Analogously, an improvement to zeroing or simply holding the control input in case of packet drops between controller and actuator is for the controller to transmit a control sequence $\mathbf{u}_k, \mathbf{u}_{k+1}, \dots, \mathbf{u}_{k+N}$ that contains not only the control $\mathbf{u}_k$ to be used at the current time instant but also a few future controls $\mathbf{u}_{k+1}, \mathbf{u}_{k+2}, \dots, \mathbf{u}_{k+N}$. In the case of packet drops between controller and actuator, the actuator can use previously received “future” control inputs in lieu of the one contained in the lost packet. The sequence of future control inputs

may be obtained, e.g., by an optimal receding horizon control strategy (Gupta et al. 2006).

Estimation with Markovian Drops

When θ_k is a Markov process, we no longer have a separation principle, and the optimal controller may depend on the drops sequence. Yet, optimal state estimates are obtained using the same TVKF presented earlier. Below, we give conditions for the stability of the error covariance when drops are governed by the Gilbert-Elliot model: $\Pr\{\theta_{k+1} = j | \theta_k = i\} = p_{ij}$, $i, j \in \{0, 1\}$.

Theorem 4 (Mo and Sinopoli 2012) *Assume that $(A, R_w^{1/2})$ is controllable, A is unstable, and the system given by the pair (A, C) is nondegenerate as discussed in Remark 1. Moreover, suppose that the transition probabilities for the Gilbert-Elliot model satisfy $p_{01}; p_{10} > 0$. Then the expected error covariance $E[P_k]$ is uniformly bounded if*

$$p_{01} > \theta_{\min}$$

and it is unbounded for some initial condition if $p_{01} < \theta_{\min}$.

Networks with Multiple Links

We now consider feedback loops that are closed over a network of communication links, each of which drops packets according to a Bernoulli process. The sensor communicates with a controller across the network, and we assume that controller and actuator are collocated. The network may be represented by a graph $\mathcal{G}$ with nodes in the set $\mathcal{V}$ and edges in the set $\mathcal{E}$, where edges are drawn between two communicating nodes. We denote by p_{ij} the probability of a drop when node i transmits to node j . Drops are assumed to be independent across links and time.

To maximize robustness with respect to drops, sensors use a Kalman filter to compute an optimal estimate for the state of the process based on their measurements and transmit this estimate across the network. When the sensors do not have access to the process input, they can take advantage of the linearity of the Kalman filter:

as the output of a Kalman filter is the sum of a term due to measurements with another term due to control inputs, sensors may compute only the contribution due to measurements and transmit it to the controller, which can subsequently add the contribution due to the control inputs. This guarantees that optimal state estimates can still be computed at the control node, even when the sensors do not know the control input (Gupta et al. 2009).

The communication in the network goes as follows. Sensors time stamp their estimates and broadcast them to all nodes in their communication ranges. After receiving information from their neighbors, nodes compare time stamps and keep only the most recent estimates. These estimates are broadcasted to all neighboring nodes. When the controller receives new information, the optimal Kalman estimate is reconstructed, taking into account the total transmission delay (learned from the packet time stamps), and a standard LQG control can be used (Gupta et al. 2009).

To determine whether or not this procedure results in a stable closed loop, one defines a *cut* $\mathcal{C} = (\mathcal{S} \Leftrightarrow \mathcal{T})$ to be a partition of the node set $\mathcal{V}$ such that the sensor node is in $\mathcal{S}$ and the controller node is in $\mathcal{T}$. The cut-set is then defined as the set of edges $(i, j) \in \mathcal{E}$ such that $i \in \mathcal{S}$ and $j \in \mathcal{T}$, i.e., the set of edges that connect the sets $\mathcal{S}$ and $\mathcal{T}$. The *max-cut probability* is then defined as

$$p_{\max\text{-cut}} = \max_{\text{all cuts } (\mathcal{S} \Leftrightarrow \mathcal{T})} \prod_{(i,j) \in \mathcal{S} \times \mathcal{T}} p_{ij}.$$

The above maximization can be rewritten as a minimization over the sums of $-\log p_{ij}$, which leads to a linear program known as the minimum cut problem in network optimization theory (Cook 1995).

Theorem 5 (Gupta et al. 2009) *Assume that $R_w, R_v > 0$, that (A, B) is stabilizable, that (A, C) is observable, and that A is unstable. Then the control and communication policy described above is optimal for quadratic costs, and the expected state covariance is bounded if and only if*

$$p_{\max\text{-cut}} \cdot (\max\{|\lambda(A)|\})^2 < 1.$$

Estimation with Controlled Communication

To actively reduce network traffic and power consumption, sensor measurements may not be sent to the remote estimator at every time step. In addition, one may have the ability to somewhat control the probability of packet drops by varying the transmit power or by transmitting copies of the same message through multiple channel realizations. This is known as *controlled communication*, and it allows the designer to establish a trade-off between communication and estimation performance.

We consider the local estimation scenario described in section “[Estimation with Local Computation](#)” with the difference that the Bernoulli drops are now modulated as follows

$$\theta_k = \begin{cases} 1 & \text{with prob. } \Lambda_k \\ 0 & \text{with prob. } 1 - \Lambda_k \end{cases}$$

where the sensor is free to choose $\Lambda_k \in [0, p_{\max}]$ as a function of the information available up to time k . With its choice, the sensor incurs on a communication cost $c(\Lambda_k)$ at time k , where $c(\cdot)$ is some increasing function that may represent, for example, the energy needed in order to transmit with a probability of drop equal to Λ_k . Note that transmission scheduling, where Λ_k is either 0 or $p_{\max}$, is a special case of this framework.

In order to choose Λ_k , the sensor considers the estimation error $\tilde{\mathbf{e}}_k := \tilde{\mathbf{x}}_{k|k} - \hat{\mathbf{x}}_{k|k-1}$ between the local and the remote estimators. This error evolves according to

$$\tilde{\mathbf{e}}_{k+1} = \begin{cases} \mathbf{d}_k & \text{with prob. } \Lambda_k \\ A\tilde{\mathbf{e}}_k + \mathbf{d}_k & \text{with prob. } 1 - \Lambda_k \end{cases}$$

where $\mathbf{d}_k$ is the innovations process arising from the standard Kalman filter in the smart sensor.

Our objective is to find a “communication policy” that minimizes the long-term average cost

$$\tilde{J} := \lim_{K \rightarrow \infty} \frac{1}{K} \mathbb{E} \left[\sum_{k=0}^{K-1} \|\tilde{\mathbf{e}}_k\|^2 + \lambda c(\Lambda_k) \right], \quad \lambda > 0, \quad (4)$$

which penalizes a linear combination of the remote estimation error variance $\mathbb{E}[\|\tilde{\mathbf{e}}_k\|^2]$ and the average communication cost $\mathbb{E}[c(\Lambda_k)]$. In this context, a *communication policy* should be understood as a rule that selects Λ_k as a function of the information available to the sensor.

When

$$(1 - p_{\max}) \max\{|\lambda(A)|\}^2 < 1,$$

there exists an optimal communication policy that chooses Λ_k as a function of $\tilde{\mathbf{e}}_k$, which may be computed via dynamic programming and value iteration (Mesquita et al. 2012). While this procedure can be computationally difficult, it is often possible to obtain suboptimal but reasonable performance with rollout policies such as the following one:

$$\Lambda_k = \arg \min_{\Lambda \in [0, p_{\max}]} [(p_{\max} - \Lambda) \tilde{\mathbf{e}}_k' A' H A \tilde{\mathbf{e}}_k + \lambda c(\Lambda)] \quad (5)$$

where H is the positive semidefinite solution to the Lyapunov equation $(1 - p_{\max})A'HA - H = -I$ (Mesquita et al. 2012).

When computing $\tilde{\mathbf{e}}_k$ and Λ_k in (5) is computationally too costly for the sensor, one may prefer to make Λ_k a function of the number of consecutive dropped packets ℓ_k . In this case, minimizing $\tilde{J}$ in (4) is equivalent to minimizing the cost

$$\bar{J} := \lim_{K \rightarrow \infty} \frac{1}{K} \mathbb{E} \left[\sum_{k=0}^{K-1} \text{trace}(\Sigma_{\ell_k}) + \lambda c(\Lambda_k) \right],$$

where

$$\Sigma_{\ell} := \sum_{m=0}^{\ell} A^m R_w A^m.$$

Since ℓ_k belongs to a countable set, one can very efficiently solve this optimization using dynamic programming (Mesquita et al. 2012).

Summary and Future Directions

Most positive results in the subject rely on the assumption of perfect acknowledgments and on actuators and controllers being collocated. Future research should address ways of circumventing these assumptions.

Networked Systems

Jorge Cortés

Department of Mechanical and Aerospace Engineering, University of California, La Jolla, CA, USA

Abstract

This article provides a brief overview on networked systems from a systems and control perspective. We pay special attention to the nature of the interactions among agents; the critical role played by information sharing, dissemination, and aggregation; and the distributed control paradigm to engineer the behavior of networked systems.

Keywords

Multiagent systems · Autonomous networks · Cooperative control · Swarms

Introduction

Networked systems appear in numerous scientific and engineering domains, including communication networks (Toh 2001), multi-robot networks (Arkin 1998; Balch and Parker 2002), sensor networks (Santi 2005; Schenato et al. 2007), water irrigation networks (Cantoni et al. 2007), power and electrical networks (Chow 1982; Chiang et al. 1995; Dörfler et al. 2013), camera networks (Song et al. 2011), transportation networks (Ahuja et al. 1993), social networks (Jackson 2010), chemical and biological networks (Kuramoto 1984; Strogatz 2003), and brain networks (Bullmore and Sporns 2009; Meunier et al. 2010; Gu et al. 2015). Their applications are pervasive, ranging from environmental monitoring, ocean sampling, and marine energy systems through search and rescue missions, high-stress deployment in disaster recovery, health monitoring of critical infrastructure to science imaging, the smart grid, and cybersecurity.

The rich nature of networked systems makes it difficult to provide a definition that, at the same time, is comprehensive enough to capture their variety and simple enough to be expressive of their main features. With this in mind, we loosely define a networked system as a “system of systems,” i.e., a collection of agents that interact with each other. These groups might be heterogeneous, composed by human, biological, or engineered agents possessing different capabilities regarding mobility, sensing, actuation, communication, and computation. Individuals may have objectives of their own or may share a common objective with others – which in turn might be adversarial with respect to another subset of agents.

In a networked system, the evolutions of the states of individual agents are coupled. Coupling might be the result of the physical interconnection among the agents, the consequence of the implementation of coordination algorithms where agents use information about each other, or a combination of both. There is diversity too in the nature of agents themselves and the interactions among them, which might be cooperative and adversarial or belong to the rich range between the two. Due to changes in the state of the agents, the network, or the environment, interactions among agents may be changing and dynamic. Such interactions may be structured across different layers, which themselves might be organized in a hierarchical fashion. Networked systems may also interact with external entities that specify high-level commands that trickle down through the system all the way to the agent level.

A defining characteristic of a networked system is the fact that information, understood in a broad sense, is sparse and distributed across the agents. As such, different individuals have access to information of varying degrees of quality. As part of the operation of the networked system, mechanisms are in place to share, transmit, and/or aggregate this information. Some information may be disseminated throughout the whole network, or in some cases, all information can be made centrally available at a reasonable cost. In other scenarios, however, the latter might turn

out to be too costly, unfeasible, or undesirable because of privacy and security considerations. Individual agents are the basic unit for decision-making but decisions might be made from intermediate levels of the networked system all the way to a central planner. The combination of information availability and decision-making capabilities gives rise to an ample spectrum of possibilities between the centralized control paradigm, where all information is available at a central planner who makes the decisions, and the fully distributed control paradigm, where individual agents only have access to the information shared by their neighbors in addition to their own.

Perspective from Systems and Control

There are many aspects that come into play when dealing with networked systems regarding computation, processing, sensing, communication, planning, motion control, and decision-making. This complexity makes their study challenging and fascinating and explains the interest that, with different emphases, they generate in a large number of disciplines. In biology, scientists analyze synchronization phenomena and self-organized swarming behavior in groups with distributed agent-to-agent interactions (Okubo 1986; Parrish et al. 2002; Conradt and Roper 2003; Couzin et al. 2005). In robotics, engineers design algorithmic solutions to help multi-vehicle networks and embedded systems coordinate their actions and perform challenging spatially distributed tasks (Arkin 1998; Committee on Networked Systems of Embedded Computers 2001; Balch and Parker 2002; Howard et al. 2006; Kumar et al. 2008). Graph theorists and applied mathematicians study the role played by the interconnection among agents in the emergence of phase transition phenomena (Bollobás 2001; Meester and Roy 2008; Chung 2010). This interest is also shared in communication and information theory, where researchers strive to design efficient communication protocols and examine the effect of topology control on group connectivity and information dissemination (Zhao and Guibas

2004; Giridhar and Kumar 2005; Lloyd et al. 2005; Santi 2005; Franceschetti and Meester 2007). Game theorists study the gap between the performance achieved by global, network-wide optimizers and the configurations that result from selfish agents interacting locally in social and economic systems (Roughgarden 2005; Nisan et al. 2007; Easley and Kleinberg 2010; Marden and Shamma 2013). In mechanism design, researchers seek to align the objectives of individual self-interested agents with the overall goal of the network. Static and mobile networked systems and their applications to the study of natural phenomena in oceans (Paley et al. 2008; Graham and Cortés 2012; Zhang and Leonard 2010; Das et al. 2012; Ouimet and Cortés 2013), rivers (Ru and Martínez 2013; Tinka et al. 2013), and the environment (DeVries and Paley 2012) also raise exciting challenges in estimation theory, computational geometry, and spatial statistics.

The field of systems and control brings a comprehensive approach to the modeling, analysis, and design of networked systems. Emphasis is put on the understanding of the general principles that explain how specific collective behaviors emerge from basic interactions; the establishment of models, abstractions, and tools that allow us to reason rigorously about complex interconnected systems; and the development of systematic methodologies that help engineer their behavior. The ultimate goal is to establish a science for integrating individual components into complex, self-organizing networks with predictable behavior. To realize the “power of many” and expand the realm of what is possible to achieve beyond the individual agent capabilities, special care is taken to obtain precise guarantees on the stability properties of coordination algorithms, understand the conditions and constraints under which they work, and characterize their performance and robustness against a variety of disturbances and disruptions.

Research Issues and How the Articles in the Encyclopedia Address Them

Given the key role played by agent-to-agent interactions in networked systems, several

encyclopedia articles, “► [Graphs for Modeling Networked Interactions](#)”, “► [Dynamic Graphs, Connectivity of](#)”, and “► [Controllability of Network Systems](#)”, deal with how their nature and effect can be modeled through graphs. This includes diverse aspects such as deterministic and stochastic interactions, static and dynamic graphs, state-dependent and time-dependent neighboring relationships, connectivity, and controllability. The importance of maintaining a certain level of coordination and consistency across the networked system is manifested in the various articles that deal with coordination tasks that are, in some way or another, related to some form of agreement. These include consensus “► [Averaging Algorithms and Consensus](#)”, formation control “► [Vehicular Chains](#)”, flocking “► [Flocking in Networked Systems](#)”, synchronization “► [Oscillator Synchronization](#)”, and distributed optimization “► [Distributed Optimization](#)”. A great deal of work, “► [Optimal Deployment and Spatial Coverage](#)” and “► [Multi-vehicle Routing](#)”, is also devoted to the design of cooperative strategies that achieve spatially distributed tasks such as optimal coverage, space partitioning, vehicle routing, and servicing. These articles explore the optimal placement of agents, the optimal tuning of sensors, and the distributed optimization of network resources. The articles “► [Estimation and Control Over Networks](#)” and “► [Distributed Estimation in Networks](#)” explore the impact that communication channels may have on the execution of estimation and control tasks over networks of sensors and actuators. The article “► [Nash Equilibrium Seeking Over Networks](#)” deals with game-theoretic scenarios that involve distributed interactions among multiple players to learn Nash equilibria under partial individual information. The growing importance in developing intelligent infrastructure of preserving the privacy of data obtained from individuals or privacy-sensitive entities in the operation of large-scale network systems is examined in “► [Privacy in Network Systems](#)”. Finally, “► [Routing in Transportation Networks](#)” provides an overview of the basics of routing control design to optimize network-level transportation objectives taking into account

complex traffic flow dynamics and driver preferences. A strong point of commonality among the contributions is the precise characterization of the scalability of coordination algorithms, together with the rigorous analysis of their correctness and stability properties. Another focal point is the analysis of the performance gap between centralized and distributed approaches in regard to the ultimate network objective.

Further information about other relevant aspects of networked systems can be found in other sections throughout this encyclopedia. Among these, we highlight the synthesis of cooperative strategies for data fusion, distributed estimation, and adaptive sampling, the analysis of the network operation under communication constraints (e.g., limited bandwidth, message drops, delays, and quantization), the distributed model predictive control, and the handling of uncertainty, imprecise information, and events via discrete event systems and triggered control.

Summary and Future Directions

In conclusion, this article has illustrated ways in which systems and control can help us design and analyze networked systems. We have focused on the role that information and agent interconnection play in shaping their behavior. We have also made emphasis on the increasingly rich set of methods and techniques that allow to provide correctness and performance guarantees. The field of networked systems is vast and the amount of work impossible to survey in this brief article. The reader is invited to further explore additional topics beyond the ones mentioned here. The monographs (Ren and Beard 2008; Bullo et al. 2009; Mesbahi and Egerstedt 2010; Alpcan and Başar 2010; Bullo 2019), edited volumes (Kumar et al. 2004; Shamma 2008; Saligrama 2008), and manuscripts (Olfati-Saber et al. 2007; Baillieul and Antsaklis 2007; Leonard et al. 2007; Kim and Kumar 2012), together with the references provided in the encyclopedia articles mentioned above, are a good starting point to undertake this enjoyable effort. Given the big impact that networked systems have, and will continue to have, in our society,

from energy and transportation through human interaction and healthcare to biology and the environment, there is no doubt that the coming years will witness the development of more tools, abstractions, and models that allow to reason rigorously about intelligent networks and for techniques that help design truly autonomous and adaptive networks.

Abstract

There has been great interest recently in “universal model-free controllers” that do not need a mathematical model of the controlled plant but mimic the functions of biological processes to learn about the systems they are controlling online, so that performance improves automatically. Neural network (NN) control has had two major thrusts: approximate dynamic programming, which uses NN to approximately solve the optimal control problem, and NN in closed-loop feedback control.

Keywords

Neural networks · Neuro-inspired control · Approximate dynamic programming · Model-free control · Neuro-adaptive control

Neural Feedback Control

The objective is to design NN feedback controllers that cause a system to follow, or track, a prescribed trajectory or path (see, e.g., Alessandri et al. (1999), Ioannou and Fidan (2006), Kosmatopoulos et al. (1995), and Werbos (1989)). Consider the dynamics of an n -link robot manipulator

$$M(q)\ddot{q} + V_m(q, \dot{q})\dot{q} + G(q) + F(\dot{q}) + \tau_d = \tau, \quad (1)$$

with $q(t) \in \mathbb{R}^n$ the joint variable vector, $M(q)$ an inertia matrix, V_m a centripetal/coriolis matrix, $G(q)$ a gravity vector, and $F(\cdot)$ representing friction terms. Bounded unknown disturbances and modeling errors are denoted by τ_d , and the control input torque is $\tau(t)$. The sliding mode control approach (Slotine and Li 1987) can be generalized to NN control systems. Given a desired trajectory $q_d \in \mathbb{R}^n$ define the tracking error $e(t) = q_d(t) - q(t)$ and the sliding variable error $r = \dot{e} + \lambda e$ with $\lambda = \lambda^T > 0$. Define the nonlinear robot function, $f(x) = M(q)(\ddot{q}_d + \lambda\dot{e}) + V_m(q, \dot{q})(\dot{q}_d + \lambda e) + G(q) + F(\dot{q})$, where the known vector $x(t)$ of measured signals is selected as, $x := [e^T \ \dot{e}^T \ q_d^T \ \dot{q}_d^T \ \ddot{q}_d^T]^T$.

NN Controller for Continuous-Time Systems

The NN controller is designed based on *functional approximation properties* of NN as shown in Lewis et al. (1999). Thus assume that $f(x)$ can be approximated by $\hat{f}(x) = \hat{W}^T \sigma(\hat{V}^T x)$ with $\hat{V}$, $\hat{W}$ the estimated NN weights. Select the control input, $\tau = \hat{W}^T \sigma(\hat{V}^T x) + K_v r - v$ with K_v a symmetric positive definite gain and $v(t)$ a robustifying function. This NN control structure is shown in Fig. 1. The outer proportional-derivative (PD) tracking loop guarantees robust behavior. The inner loop containing the NN is known as a feedback linearization loop, and the NN effectively learns the unknown dynamics online to cancel the nonlinearities of the system. Let the estimated sigmoid Jacobian be $\hat{\sigma}' \equiv \frac{d\sigma(z)}{dz}|_{z=\hat{V}^T x}$. Then the NN weight tuning laws are provided by

Neuro-inspired Control, Fig. 1 Neural network robot controller

$$\begin{aligned}\dot{\hat{W}} &= F\hat{\sigma}r^T - F\hat{\sigma}'\hat{V}_{xr}^T - kF\|r\|\hat{W}, \\ \dot{\hat{V}} &= Gx(\hat{\sigma}\hat{W}r)^T - kG\|r\|\hat{V},\end{aligned}$$

with any constant symmetric matrices $F, G > 0$, and scalar tuning parameter $k > 0$.

NN Controller for Discrete-Time Systems

Most feedback controllers today are implemented on digital computers. This requires the specification of control algorithms in discrete-time or digital form (Lewis et al. 1999). To design such controllers, one may consider the discrete-time dynamics $x_{k+1} = f(x_k) + g(x_k)u_k$ with unknown functions $f(\cdot), g(\cdot)$. The digital NN controller derived in this situation has the form of a feedback linearization controller shown in Fig. 1. One can derive tuning algorithms, for a discrete-time neural network controller with L layers, that guarantee system stability and robustness (Lewis et al. 1999). For the i -th layer the weight updates are of the form,

$$\begin{aligned}\hat{W}_i(k+1) &= \hat{W}_i(k) - \alpha_i \hat{\phi}_i(k) \hat{y}_i^T(k) - \Gamma \\ &\quad \left\| I - \alpha_i \hat{\phi}_i(k) \hat{\phi}_i(k)^T \right\| \hat{W}_i(k)\end{aligned}$$

where $\hat{\phi}_i(k)$ are the output functions of layer i , $0 < \Gamma < 1$ is a design parameter and

$$\hat{y}_i(k) = \begin{cases} \hat{W}_i^T \hat{\phi}_i(k) + K_v r(k) & \text{for } i = 1, \dots, L-1, \\ r(k+1) & \text{for } i = L \end{cases}$$

with $r(k)$ a filtered error.

Feed-Forward Neurocontroller

Industrial, aerospace, DoD, and MEMS assembly systems have actuators that generally contain deadzone, backlash, and hysteresis. Since these actuator nonlinearities appear in the feed-forward loop, the NN compensator must also appear in the feedforward loop. This design is significantly more complex than for feedback NN controllers. Details are given in Lewis et al. (2002). Feed-forward controllers can offset the effects of deadzone if properly designed. It can be shown that a NN deadzone compensator has the structure shown in Fig. 2. The NN compensator consists of two NNs. NN II is in the direct feed-forward control loop, and NN I is not directly in the control loop but serves as an observer to estimate the (unmeasured) applied torque $\tau(t)$. The feedback stability and performance of the NN deadzone compensator have been rigorously proven using nonlinear stability proof techniques. The two NN were each selected as having one tunable layer, namely, the output weights. The activation functions were set as a basis by selecting fixed random values for the first-layer weights. To guarantee

Neuro-inspired Control, Fig. 2 Feed-forward NN for deadzone compensation

stability, the output weights of the inversion NN II (subscript i denotes weights and sigmoids of the inversion) and the estimator NN I should be tuned, respectively, as

$$\begin{aligned}\dot{\hat{W}}_i &= T\sigma_i(V_i w)r^T \hat{W}^T \sigma'_i(V^T u)V^T \\ &\quad - k_1 T \|r\| \hat{W}_i - k_2 T \|r\| \|\hat{W}_i\| \hat{W}_i, \\ \dot{\hat{W}} &= -S\sigma'(V^T u)V^T \hat{W}_i \sigma_i(V_i^T w)r^T \\ &\quad - k_1 S \|r\| \hat{W},\end{aligned}$$

with design matrices $T, S \succ 0$ and tuning gains k_1, k_2 .

A continuous Robust Integral of the Sign of the Error structure has been used in Patre et al. (2008) to compensate for the unstructured uncertainties.

Approximate Dynamic Programming for Feedback Control

The current status of work in approximate dynamic programming (ADP) for feedback

control is given in Lewis and Liu (2012). ADP is a form of reinforcement learning (RL) based on an actor/critic structure (Bertsekas and Tsitsiklis 1996). RL is a class of methods used in machine learning to methodically modify the actions of an agent based on observed responses from its environment (Sutton and Barto 1998). The actor/critic structures are RL systems that have two learning structures: A critic network evaluates the performance of a current action policy, and based on that evaluation, an actor structure updates the action policy. Adaptive optimal controllers (Lewis et al. 2012) have been proposed by adding optimality criteria to an adaptive controller or adding adaptive characteristics to an optimal controller.

Optimal Adaptive Control of Discrete-Time Nonlinear Systems

Consider a class of discrete-time systems described by the deterministic nonlinear dynamics in the affine state space difference equation form

$$x_{k+1} = f(x_k) + g(x_k)u_k, \quad (2)$$

with state $x_k \in \mathbb{R}^n$ and control input $u_k \in \mathbb{R}^m$. A deterministic control policy is defined as a function from state space to control space $\mathbb{R}^n \rightarrow \mathbb{R}^m$. That is, for every state x_k , the policy defines a control action $u_k = h(x_k)$ as a feedback controller. Define a deterministic cost function that yields the value function $V(x_k) = \sum_{i=k}^{\infty} \gamma^{i-k} r(x_i, u_i)$, with $0 < \gamma \leq 1$ a discount factor, $Q(x_k)$, $R >$ and $u_k = h(x_k)$ a prescribed feedback control policy. The optimal value is given by Bellman's optimality equation, $V^*(x_k) = \min_{h(\cdot)} (r(x_k, h(x_k)) + \gamma V^*(x_{k+1}))$, which is the discrete-time Hamilton-Jacobi-Bellman (HJB) equation. Two forms of RL can be based on policy iteration (PI) and value iteration (VI). For temporal difference learning, PI is written as follows in terms of the deterministic Bellman equation. where ϵ_{ac} is a small number that checks the algorithm convergence. Value iteration is similar, but the policy evaluation procedure is performed as $V_{i+1}(x_k) = r(x_k, h_i(x_k)) + \gamma V_i(x_{k+1})$. In value iteration we can select any initial control policy, not necessarily admissible or stabilizing. In the control system, the critic and the actor NNs are tuned online using the observed data $(x_k, x_{k+1}, r(x_k, h_i(x_k)))$ along the system trajectory. The critic and actor are tuned sequentially in both the PI and the VI. That is, the weights of one neural network are held constant, while the weights of the other are tuned until convergence. This procedure is repeated until both neural networks have converged. Thus, the controller learns the optimal controller online. The convergence of value iteration using two neural networks for the discrete-time nonlinear

system (2) is proven in Al-Tamimi et al. (2008). Design of an ADP controller that uses only output feedback is given in Lewis and Vamvoudakis (2011).

Optimal Adaptive Control of Continuous-Time Nonlinear Systems

RL is considerably more difficult for continuous-time systems than for discrete-time systems, and fewer results are available. This subsection will provide the formulation of optimal control problem followed by an offline PI algorithm provided in Abu-Khalaf and Lewis (2005) that will give us the structure for the proposed online algorithms that follow. Consider the following nonlinear time-invariant affine in the input dynamical system given by

$$\dot{x}(t) = f(x(t)) + g(x(t))u(t); x(0) = x_0,$$

where $x(t) \in \mathbb{R}^n$, $f(x(t)) \in \mathbb{R}^n$, $g(x(t)) \in \mathbb{R}^{n \times m}$ and control input $u(t) \in \mathbb{R}^m$. We assume that $f(0) = 0$, $f(x) + g(x)u$ is Lipschitz continuous on a set $\Omega \subset \mathbb{R}^n$ that contains the origin and that the system is stabilizable on Ω , that is, there exists a continuous control function $u(t) \in U$ such that the system is asymptotically stable on Ω . Define the infinite horizon integral cost $\forall t \geq 0$

$$V(x_t) = \int_t^{\infty} r(x(\tau), u(\tau)) d\tau, \quad (3)$$

with $Q(x)$ positive definite and $R \in \mathbb{R}^{m \times m}$ a symmetric positive definite matrix. For any admissible control policy if the associated cost (3) is C^1 , then an infinitesimal version is the Bellman equation, and the optimal cost function $V^*(x)$ is defined by $V^*(x_0) = \min_u \int_0^{\infty} r(x, u) d\tau$, which satisfies the HJB equation. By employing the stationarity condition, the optimal control function for the given problem is

$$u^*(x) = -\frac{1}{2} R^{-1} g^T(x) \frac{\partial V^*(x)}{\partial x}. \quad (4)$$

Algorithm 1 PI for discrete-time systems

- 1: **procedure**
 - 2: Given admissible policies $h_0(x_k)$.
 - 3: **while** $\|V^{h_i} - V^{h_{i-1}}\| \geq \epsilon_{ac}$ **do**
 - 4: Solve for the value $V_{(i)}(x)$ using $V_{i+1}(x_k) = r(x_k, h_i(x_k)) + \gamma V_i(x_{k+1})$.
 - 5: Update the control policy $h_{(i+1)}(x_k)$ using $h_{i+1}(x_k) = \arg \min_{h(\cdot)} (r(x_k, h(x_k)) + \gamma V_{i+1}(x_{k+1}))$.
 - 6: $i := i + 1$
 - 7: **end while**
 - 8: **end procedure**
-

Inserting the optimal control (4) into the Bellman equation one obtains the formulation for HJB equation in terms of $\frac{\partial V^*(x)}{\partial x}$ and with boundary condition $V^*(0) = 0$,

$$0 = r(x, u^*) + \frac{\partial V^*(x)}{\partial x} (f(x) + g(x)u^*), \quad (5)$$

which for the linear case becomes the well-known Riccati equation. In order to find the optimal control solution for the problem, one needs to solve the HJB equations (5) for the value function and then substitute in (4) to obtain the optimal control. However, due to the nonlinear nature of the HJB equation finding, its solution is generally difficult or impossible. The following PI algorithm is an iterative algorithm for solving optimal control problems and will give us the structure for the online learning algorithm: A PI algorithm that solves online

Algorithm 2 PI for continuous-time systems

- 1: **procedure**
 - 2: Given admissible policies $u^{(0)}$.
 - 3: **while** $\|V^{u^{(i)}} - V^{u^{(i-1)}}\| \geq \epsilon_{ac}$ **do**
 - 4: Solve for the value $V^{(i)}(x)$ using Bellman's equation, $Q(x) + \frac{\partial V^{u^{(i)}}}{\partial x} (f(x) + g(x)u^{(i)}) + u^{(i)T} R u^{(i)} = 0$, $V^{u^{(i)}}(0) = 0$.
 - 5: Update the control policy $u^{(i+1)}$ using, $u^{(i+1)} = -\left(\frac{1}{2}R^{-1}g^T(x)\frac{\partial V^{u^{(i)}}}{\partial x}\right)^T$.
 - 6: $i := i + 1$
 - 7: **end while**
 - 8: **end procedure**
-

the HJB equation without full information of the plant dynamics is proposed in Vrabie et al. (2009) where the Bellman equation is proved to be equivalent to the *integral RL form* with an optimal value given for some $T > 0$ as, $V^*(x(t)) = \arg \min_u \int_t^{t+T} r(x(\tau), u(\tau))d\tau + V^*(x(t+T))$. Therefore, the temporal difference error for continuous-time systems can be defined as $e(t : t+T) = \rho(t : t+T) + V(x(t+T)) - V(x(t))$, with $\rho(t : t+T) \equiv \int_t^{t+T} r(x(\tau), u(\tau))d\tau$ without any information of the plant dynamics. The IRL controller just given tunes the critic neural

network to determine the value while holding the control policy fixed. The IRL algorithm can be implemented online by RL techniques using value function approximation $\hat{V}(x) = \hat{W}_1^T \phi(x)$ in a critic approximator network. Using that approximation in the PI algorithm, one can use batch least squares or recursive least squares to update the value function, and then on convergence of the value parameters, the action is updated. The work in Vamvoudakis and Lewis (2010) presents a way of finding the optimal control solution in a synchronous manner along with stability and convergence guarantees but with known dynamics. This procedure is more nearly in line with accepted practice in adaptive control. Synchronous online learning algorithms that avoids the knowledge of the dynamics are proposed in Kamalapurkar et al. (2018) and Vamvoudakis et al. (2014).

On-Policy Versus Off-Policy Regulation and Tracking Methods

Finally, algorithms that are used to solve optimal control problems are categorized in two classes of neuro-control methods, namely, on-policy and off-policy methods. On-policy methods evaluate or improve the same policy as the one that is used to make decisions. In off-policy methods, these two functions are separated. The policy used to generate data, called the behavior policy, may in fact be unrelated to the policy that is evaluated and improved, called the estimation policy or target policy. The learning process for the target policy is online, but the data used in this step can be obtained offline by applying the behavior policy to the system dynamics. The off-policy methods are data efficient and fast since a stream of experiences obtained from executing a behavior policy is reused to update several value functions corresponding to different estimation policies. Moreover, off-policy algorithms (Jiang and Jiang 2017) take into account the effect of probing noise needed for exploration. A survey on on-policy and off-policy methods for regulation and tracking is provided in our recent work in Kiumarsi et al. (2018) and Vamvoudakis et al. (2015).

Games

RL techniques have been applied to design adaptive controllers that converge to the solution of two-player zero-sum games in Vamvoudakis and Lewis (2012) and Vrabie et al. (2012), of multi-player nonzero-sum games in Vamvoudakis and Lewis (2011a, b) and Vamvoudakis et al. (2012), and of Stackelberg games in Vamvoudakis et al. (2019). In these cases, the adaptive control structure has multiple loops, with action networks and critic networks for each player. The adaptive controller for zero-sum games finds the solution to the H-infinity control problem online in real time. This adaptive controller does not require any systems dynamics information. The magazine article (Vamvoudakis et al. 2017) presents a family of algorithms that show how to solve multiplayer games online by adaptive learning in real time using data measured along the trajectories of the players. The full dynamics of the players do not need to be known for these online solution techniques. This is a truly dynamic framework for team decision-making, since players or teams can change their objectives or optimality criteria on the fly, and the new strategies for all players, appropriate to the new situation, are then recomputed in real time.

Summary and Future Directions

This book entry discusses some neuro-inspired control techniques. These controllers have multi-loop, multi-timescale structures and can learn the solutions to Hamilton-Jacobi design equations such as the Riccati equation online without knowing the full dynamical model of the system. An interesting and important open research direction is to develop novel neuro-inspired approaches for feedback control of nonlinear systems with high-dimensional inputs and unstructured input data, i.e., by using deep neural networks. Deep neural networks can approximate a more accurate structure of the value function and avoid divergence of the algorithm and consequently instability of the feedback control system.

Noise Spectra in MEMS Coriolis Vibratory Gyros

Robert T. M'Closkey

Mechanical and Aerospace Engineering,
Samueli School of Engineering and Applied
Science, University of California, Los Angeles,
CA, USA

Abstract

Coriolis vibratory gyros possess vibrating elements whose motion is modified due to rotation of the sensor. Maturation of wafer-scale fabrication techniques has led to the production of a diverse family of sensors based around miniature resonators with integrated pick-offs, forcers, and signal conditioning electronics. This entry summarizes the common features found in the noise spectra of the angular rate estimates obtained from such devices. The angle random walk and angle white noise figures of merit are described, and the noise spectra relation to the Allan variance is also discussed.

Introduction

Wafer processing techniques have matured to the point where miniature, multi-degree-of-freedom, precision mechanical structures can be routinely fabricated. Due to the challenge

of fabricating structures with freely rotating elements at small scales, sensitivity to angular motion is achieved through the coupling to two resonant modes in an elastic structure. Thus, all microelectromechanical (MEMS) gyros fall into a class of angular rate sensors called Coriolis vibratory gyros, or CVGs. A variety of MEMS CVG designs have emerged, from traditional tuning forks fabricated from crystalline quartz to lumped-mass/stiffness structures and distributed-mass/stiffness axisymmetric resonators fabricated from silicon and fused silica. A great deal of effort is involved in designing the structures to tailor the mode shapes and modal frequencies of the pair of modes which are exploited for angular rate sensing while simultaneously minimizing the influence of other modes which inevitably appear. Examples of resonators that have been produced by the research community include planar rings (Ayazi and Najafi 2001; Shcheglov and Challoner 2006; Yang et al. 2015; Su et al. 2014; Ge and M'Closkey 2017), hemispheres and hemi-toroids (Bernstein et al. 2013; Prikhodko et al. 2011; Cho et al. 2014; Horning et al. 2014), and tuning forks (Weinberg and Kourepenis 2006; Trusov et al. 2011). Axisymmetric designs typically produce modal degeneracy, whereas tuning fork-type resonators exhibit some separation in the modal frequencies of the modes of interest.

CVG performance is determined by the noise spectra of the extracted angular rate signals. This entry focuses on case where external noise sources exist at the input and output of the resonator's electromechanical transfer function. This captures many sources of noise including contributions from buffering electronics, which are naturally modeled as appearing at the transfer function output, and mechanical-thermal noise (Gabrielson 1993), digital-to-analog converter noise, and vibration of the sensor case, which are examples of sources appearing at the transfer function input. Thus, the presentation is somewhat generic. One aspect which is not included in the analysis is the modeling of sources of long-term drift in the sensor offset (bias) signals. This is subject of intense research and must be approached separately

for each technology since it can depend on the resonator packaging, resonator material, thermal environment, residual stress, package vacuum level and stability, and additional factors.

Resonator Model

Ignoring all but the modes of interest, the differential equation written in sensor case-fixed coordinates is described by

$$M\ddot{x} + (D + \Omega\alpha S)\dot{x} + Kx = f \quad (1)$$

where M , D , and K are 2×2 positive definite mass, damping, and stiffness matrices, respectively,

$$M = \begin{bmatrix} m_1 & m_3 \\ m_3 & m_2 \end{bmatrix}, \quad D = \begin{bmatrix} d_1 & d_3 \\ d_3 & d_2 \end{bmatrix}, \quad K = \begin{bmatrix} k_1 & k_3 \\ k_3 & k_2 \end{bmatrix},$$

Ω is the angular rotation rate of the sensor case, S is the skew-symmetric matrix

$$S = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix},$$

α captures the "strength" of the Coriolis coupling, which depends on the resonator design, and $f = [f_1, f_2]^T$ are the forces acting on the two degrees of freedom x_1 and x_2 that comprise the vector x . Noise sources will be added to the model later. In actual resonators, measurements of each coordinate are available and, depending on the transduction method, may be proportional to x or $\dot{x}$. Furthermore, it is assumed that the forces f are co-located with the coordinates. In an ideal CVG, the mass, stiffness, and damping matrices in (1) are diagonal, and so the two coordinates are only coupled through the Coriolis term. In practice, the off-diagonal terms in these matrices are non-zero and are the source of various *in-phase* and *quadrature* biases, or offsets, in the angular rate estimate extracted from the sensor. Nevertheless, it can be assumed that the coordinates are nearly decoupled, with the exception of the Coriolis term, and so that it makes sense to refer to *the* resonant mode associated

with a given channel, i.e., x_1/f_1 channel has only one resonant mode with frequency $\omega_1 := \sqrt{k_1/m_1}$, the x_2/f_2 channel has another resonant mode with frequency $\omega_2 := \sqrt{k_2/m_2}$, and the “cross-channels” x_1/f_2 and x_2/f_1 are essentially zero.

MEMS CVGs operate in one of two modes: an open-loop configuration in which the rotation-induced response is measured in one degree of freedom or a closed-loop configuration in which the rotation-induced response is attenuated with feedback. In the latter case, the control effort is related to the rotation rate. Whichever configuration is used, though, the companion degree of freedom is forced into a fixed amplitude sinusoidal response. The excitation of this degree of freedom is necessary for the sensor to function since its motion acts as a carrier signal whose amplitude is modulated by the sensor’s angular rate. It will be assumed that the x_1 coordinate is used for the sensor excitation. In order to build an appreciable amplitude in this coordinate, a feedback loop is used to drive the x_1/f_1 channel resonant mode at its natural frequency. The controllers for this task are typically phase-locked loops or automatic gain control filters. The design of these controllers is standard and do not present any particular challenges. It will be assumed that the excitation controller specifies f_1 such that $x_1 = a \cos(\omega_1 t)$, where ω_1 is close to the natural frequency of the x_1/f_1 channel resonant mode. This effectively removes the x_1 coordinate from the analysis. The differential equation for the second coordinate is

$$m_2 \ddot{x}_2 + d_2 \dot{x}_2 + k_2 x_2 = f_2 + d \quad (2)$$

where d is the “disturbance” to the x_2 coordinate created by the excitation loop driving the x_1 coordinate,

$$d = a(\omega_1^2 m_3 - k_3) \cos(\omega_1 t) + a\omega_1 (d_3 - \alpha \Omega(t)) \sin(\omega_1 t). \quad (3)$$

The transfer function P is defined as $P := 1/(m_2 s^2 + d_2 s + k_2)$.

Open-Loop CVG

The open-loop CVG does not use feedback on the x_2 coordinate so $f_2 = 0$. The block diagram is shown below:

where noise sources n_i and n_o , which are assumed to be independent, have been added at the input and output, respectively, of P , and the transduction gains K_o and K_i merely convert the resonator motion into a voltage (unit V) or a voltage into a force. Without loss of generality, the noise sources are located at points where they are expressed in volts. The scale factor is determined assuming the noises are zero and the angular rate is constant, $\bar{\Omega}$,

$$x_2(t) = |P(j\omega_1)|a(\omega_1^2 m_3 - k_3) \cos(\omega_1 t + \angle P(j\omega_1)) + |P(j\omega_1)|a\omega_1 (d_3 - \alpha \bar{\Omega}) \sin(\omega_1 t + \angle P(j\omega_1)) \quad (4)$$

The angular rate is recovered by synchronous demodulation of $y = K_o x_2$: it is multiplied by $\sin(\omega_1 t + \phi)$, where the phase $\phi = \angle P(j\omega_1)$ is chosen to maximize the component with $\bar{\Omega}$ and then low-pass filtered with h_{lp} to produce the “DC” signal, $(K_o x_2(t) \sin(\omega_1 t + \phi))$

$$= \frac{1}{2} K_o |P(j\omega_1)|a\omega_1 (d_3 - \alpha \bar{\Omega})$$

where $*$ denotes convolution. The term multiplying $\bar{\Omega}$ is the inverse of the *open-loop scale factor*,

$$\gamma_{ol}^{-1} = -\frac{1}{2} K_o |P(j\omega_1)|a\omega_1 \alpha.$$

Multiplication of the demodulated signal by γ_{ol} produces the constant rate $\bar{\Omega}$ plus the *in-phase* bias $-d_3/\alpha$. This bias term, which is due to dissipation in the resonator, is indistinguishable

from an applied angular rate. The quadrature bias is (ideally) perfectly rejected by the synchronous demodulation. In practice, the bias terms slowly drift with time due to slowly changing resonator dynamics. The root causes of such drift, and how to mitigate them, is an active area of research in MEMs CVG development. The synchronous demodulation can also be subject to phase errors which means that the quadrature bias can leak into the in-phase measurement, thereby adding further sources of drift. In terms of noise analysis, though, these slow drifts impact the low frequency portion of the angular rate noise spectrum and are not the subject of analysis in this entry.

When a sinusoidal angular rate $\Omega(t) = \Omega_0 \cos(\tilde{\omega}t)$ is applied to the sensor, the modulation of Ω by $\sin(\omega_1 t)$ in (3) produces sidebands at frequencies $\omega_1 \pm \tilde{\omega}$. The amplitude and phase response of x_2 should be essentially equal at these frequencies to ensure that the scale factor is not dependent on the frequency of the angular rate input over the range of interest. In other words it is desired $P(j\omega_1 + \tilde{\omega}) \approx P(j\omega_1 - \tilde{\omega}) \approx P(j\omega_1)$; therefore, ω_1 should be somewhat smaller than ω_2 so that ω_1 resides in the “flat” portion of the frequency response of P . This is the motivation in open-loop CVGs to design the modal frequencies so that there is a substantial difference between them and with the frequencies ordered such that $\omega_1 < \omega_2$. The bandwidth of estimated angular rate signal is then established by the low-pass filter h_{lp} that is used in the demodulator. The bandwidth of h_{lp} is denoted ω_{lp} .

The mean-square spectral density of y , denoted S_y , due to noise sources n_i and n_o is given by $S_y = S_o + |K_o P K_i|^2 S_i$, where S_i and S_o are the spectral densities of n_i and n_o , respectively. It is assumed that S_i and S_o are constant in the frequency band $[\omega_1 - \omega_{lp}, \omega_1 + \omega_{lp}]$, thus, S_y is also constant in this band since $|K_o P K_i| \approx |K_o P(j\omega_1) K_i|$ over this band. In practice, the spectrum of y is directly measured with the effect of the noise sources aggregated into a single value for the root spectral density which will be denoted v_o . Demodulating y produces the spectrum $\frac{1}{4} (S_y(\omega_1 + \omega) + S_y(\omega_1 - \omega)) = \frac{1}{2} v_o^2$ at the output of h_{lp} and the subsequent multiplication

by the scale factor yields the following expression for the *noise-equivalent rate*, or S_{NER} ,

$$S_{\text{NER}}(\omega) = \frac{1}{2} \gamma_{ol}^2 v_o^2 \quad \omega \in [0, \omega_{lp}] \quad (5)$$

The open-loop CVG model can be summarized as follows:

where the spectral density of n_{NER} is given by (5).

Closed-Loop CVG

Unlike open-loop CVGs in which $\omega_1 < \omega_2$, closed-loop CVGs are designed so that $\omega_1 = \omega_2$ (a condition of *modal degeneracy*). The motivation is to create a relatively large mechanical response of the x_2 coordinate due to angular rate inputs. This occurs because the angular rate-modulated term $\Omega(t) \sin(\omega_1 t)$ in (3) drives the x_2 coordinate with a spectrum that is in a neighborhood of the modal frequency, ω_2 , which has the effect of increasing the signal-to-noise ratio of y with respect to the output noise source, n_o . The response of x_2 in a neighborhood of ω_2 is frequency dependent, though, especially in resonators with high quality factors, so some kind of equalization is necessary – the equalizing filter is essentially an inverse of the plant, which is most conveniently achieved using feedback. Thus, the closed-loop CVG operates by feeding back y to null the effect of the angular rate on the response of the x_2 coordinate as shown in the block diagram below

For sufficiently high loop gain, the control effort u cancels d ; thus, u is demodulated in order to

recover a signal proportional to Ω . The feedback also keeps the x_2 coordinate in a linear regime with respect to electrostatic forces and the elastic material properties, which may not be the case if the modally degenerate resonator is operated open-loop. Another difference with the open-loop CVG is associated with the plant model itself. The open-loop CVG often uses a charge amplifier if the sensing pick-offs are capacitive or piezoelectric in nature. This configuration yields a measurement that is proportional to displacement. While it is possible to use a charge amplifier in a closed-loop CVG, a common technique for buffering the capacitive pick-offs is to employ a transresistance amplifier, which produces a measurement proportional to velocity. This is an advantage in closed-loop CVGs because the feedback filter is designed to dampen the x_2 coordinate resonance; if displacement is measured, then the controller has to provide the necessary phase-lead filtering; however, if velocity is measured, then the controller is a simpler filter since the phase-lead is obtained via the measurement. Hence, in the closed-loop CVG, it is assumed that sP is the plant to be controlled. In terms of analyzing the closed-loop system, the controller can be assumed to be a simple gain, C .

Ignoring the noise sources for the moment and assuming a constant angular rate, $\bar{\Omega}$, $u = -K_i^{-1}d$

for sufficiently large loop gain so demodulating u yields

$$\begin{aligned} h_{lp}(t) * (u(t) \sin(\omega_1 t + \phi)) \\ = -\frac{1}{2} K_i^{-1} a \omega_1 (d_3 - \alpha \bar{\Omega}) \end{aligned}$$

where the demodulation phase ϕ is chosen to maximize the $\bar{\Omega}$ component and reject the quadrature term. The closed-loop scale factor is

$$\gamma_{cl}^{-1} = \frac{1}{2} K_i^{-1} a \omega_1 \alpha$$

The sensor bandwidth, denoted ω_c , is not determined by the demodulation low-pass filter h_{lp} as it is in the open-loop CVG. Instead it is determined by the frequency interval over which the loop gain $K_o s P K_i C$ has magnitude greater than one (see Fig. 1). The sensor model in this case is $\omega_c/(s + \omega_c)$, where ω_c is defined in Fig. 1.

With the noise sources present, it is assumed again that S_i and S_o are constants; however, it is necessary to distinguish the input and output noise intensities (they cannot be aggregated into a single constant) because of the frequency dependence caused by P ; thus, $S_i(\omega) = v_i^2$ and $S_o(\omega) = v_o^2$, both given in V^2/Hz units. The mean-square spectral density of u , denoted S_u , is given by

Noise Spectra in MEMS Coriolis Vibratory Gyros,

Fig. 1 Loop gain magnitude, $|K_o s P K_i C|$. The closed-loop bandwidth, ω_c , is one half of the interval over which the loop gain magnitude is greater than one

$$S_u = \left| \frac{\tilde{P}C}{1 - \tilde{P}C} \right|^2 v_i + \left| \frac{C}{1 - \tilde{P}C} \right|^2 v_o, \quad (6)$$

where $\tilde{P} = K_o s P K_i C$ denotes the product of the forward path elements. It is possible to rewrite (6) as follows:

$$S_u(\omega) = |C(j\omega_2)|^2 v_o^2 \frac{(\omega_2^2 - \omega^2)^2 + (2\omega_e \omega)^2}{(\omega_2^2 - \omega^2)^2 + (2\omega_c \omega)^2}, \quad (7)$$

where ω_e is defined as the effective bandwidth

$$\omega_e = \omega_m \sqrt{1 + (p v_i / v_o)^2}$$

and ω_m is the mechanical bandwidth of the x_2 mode (the mechanical bandwidth is defined as the product of the damping ratio and modal frequency and so is simply the exponential decay rate of the x_2 mode). The parameter p is the maximum gain of $\tilde{P}$. The effective bandwidth captures the relative importance of the two noise sources: if $\omega_e \rightarrow \omega_m$, then n_i can be ignored in the analysis, whereas if $\omega_e \rightarrow \infty$, then n_o can be ignored in the analysis. Although it v_i does not appear explicitly in the way S_u is written in (7), if $\omega_e \rightarrow \infty$, it can be shown that $S_u \rightarrow v_i^2$ because the closed-loop bandwidth, mechanical bandwidth, maximum gain of $\tilde{P}$, and controller gain $|C(j\omega_2)|$ satisfy the relationship

$\omega_c = \omega_m p |C(j\omega_2)|$. Introducing this additional notation cannot be avoided because if the modal damping goes to zero, then there is always a frequency band around ω_2 where the input noise dominates the noise spectrum of angular rate estimate.

The spectrum of the demodulated signal at the output of h_{lp} is $\frac{1}{4} (S_u(\omega_1 + \omega) + S_u(\omega_1 - \omega))$. In practice, the frequency of the demodulator differs from the modal frequency of the x_2 coordinate, i.e., $\omega_1 \neq \omega_2$; however, this complicates the expression for the noise-equivalent rate S_{NER} ; thus, the special case will be assumed in which $\omega_1 = \omega_2$,

$$\begin{aligned} S_{\text{NER}}(\omega) &= \frac{1}{4} \gamma_{cl}^2 (S_u(\omega_2 + \omega) + S_u(\omega_2 - \omega)) \\ &\approx \frac{1}{2} \gamma_{cl}^2 |C(j\omega_2)|^2 v_o^2 \frac{\omega^2 + \omega_e^2}{\omega^2 + \omega_c^2} \end{aligned} \quad (8)$$

The approximation is valid assuming $\omega_c \ll \omega_1$, which is always satisfied in practice. Figure 2 shows $S_{\text{NER}}^{\frac{1}{2}}$ for the cases when only one noise source is present and also when both noise sources are present and contribute trends to the noise spectrum. The figure also elucidates the roles of ω_m , ω_e and ω_c . Thus, the closed-loop CVG model can be summarized as follows:

Noise Spectra in MEMS Coriolis Vibratory Gyros,

Fig. 2 Noise equivalent rate spectrum in the closed-loop CVG when the modal frequencies are matched

where the spectral density of n_{NER} is given by (8).

Angle Random Walk and Allan Variance Representation

The mean-square spectral density of the angular rate noise defines the CVG performance with regard to the “external” noise sources n_i and n_o . As mentioned earlier, this is not a complete description of the angular rate noise since changes in the resonator itself create low frequency (long period) variations in the angular rate bias/offset signal. Modeling these signals is much more resonator-specific as opposed to the analysis covered here which is agnostic with regard to the particular resonator design. Ignoring the offset variation, it is still useful to convert S_{NER} into alternative metrics that find common use in the navigation community. One such metric is the sensor’s angle random walk (ARW) figure, and another metric is the Allan variance (AV), which is often presented in graphical form. Both ARW and AV can be analyzed using the following block diagram as an aid,

where the impulse response for the ARW computation is a “moving integral” and the impulse response for the AV computation is a time-averaged difference of the rate signal and its time-delayed copy (the averaging interval and time delay being equal),

$$h_{\text{ARW}}(t) = \begin{cases} 1 & t \in [0, \tau] \\ 0 & \text{otherwise} \end{cases},$$

$$h_{\text{AV}}(t) = \begin{cases} \frac{1}{\tau} & t \in [0, \tau] \\ -\frac{1}{\tau} & t \in [\tau, 2\tau] \\ 0 & \text{otherwise} \end{cases}.$$

Here, τ is the integration or averaging interval. The quantity of interest is the variance (denoted

σ_{AV}^2 and σ_{ARW}^2) of the signal produced by such filtering as a function of τ . For the ARW computation, the output has units of angle, whereas the AV computation has units of angular rate. The mean-square value of the output in the ARW computation is given by

$$\sigma_{\text{ARW}}^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{\text{NER}}(\omega) |h_{\text{ARW}}(\omega)|^2 d\omega. \quad (9)$$

The expression for σ_{AV}^2 is obtained by simply replacing h_{ARW} with h_{AV} . Evaluating (9) for the open-loop CVG yields $\sigma_{\text{ARW}}^2 = S_{\text{NER}}(0)\tau$. The ARW figure associated with the CVG is the value of σ_{ARW} when τ is equal to 1 h and represents the standard deviation (uncertainty) associated with computed change in angle of the sensor obtain by integrating its angular rate measurement for 1 h. The expression for σ_{ARW}^2 in the closed-loop CVG has an additional term, $\sigma_{\text{ARW}}^2 = S_{\text{NER}}(0)\tau + S_{\text{NER}}(0)\omega_c/(\omega_e)^2$. The constant term dominates the variance value for integration times $\tau < \omega_c/(\omega_e)^2$ and for this reason is the *angle white noise* (AWN) figure associated with the CVG. AWN is a consequence of the output noise source n_o creating the “phase-lead” profile of S_{NER} . Nevertheless, for sufficiently long integration times, $\sigma_{\text{ARW}}^2 \approx S_{\text{NER}}(0)\tau$, and so an ARW figure can also be quoted the closed-loop CVG.

The Allan variance computation for the open-loop CVG yields $\sigma_{\text{AV}}^2 = S_{\text{NER}}(0)/\tau$, and the closed-loop AV is closely approximated by $\sigma_{\text{AV}}^2 = S_{\text{NER}}(0)\frac{1}{\tau} + \frac{3}{2}S_{\text{NER}}(0)\frac{\omega_c}{\omega_e^2}\frac{1}{\tau^2}$. Common practice is to graph σ_{AV} (Allan deviation) versus τ on log-log axes. This yields the familiar “ $-1/2$ ” slope associated with the ARW for both open-loop and closed-loop CVGs and the “ -1 ” slope associated with the AWN at smaller integration times for the closed-loop CVG. These trends are shown in Fig. 3. In the closed-loop CVG, the asymptotes cross at an integration time of $\tau = \frac{3}{2}\frac{\omega_c}{\omega_e^2}$. These graphs assume that the input noise does not dominate the S_{NER} spectrum in the closed-loop sensor, i.e., the S_{NER} has a phase-lead characteristic and $\omega_e < \omega_c$ in particular. If the input noise does dominate the angular rate noise spectrum, then S_{NER} looks like the spectrum associated with the

Noise Spectra in MEMS Coriolis Vibratory Gyros,
Fig. 3 ARW and AWN trends in the root Allan variance, σ_{AV}

open-loop analysis, and the AWN asymptote is not present in the AV graph.

Summary and Future Directions

This entry focused on the analysis of noise spectra for open- and closed-loop solid state gyros, also called Coriolis vibratory gyros. The resonators in open-loop CVGs are designed so that the two modes exploited for angular rate sensing have separated modal frequencies. The consequence is that the noise-equivalent-rate spectrum is essentially constant across the bandwidth of the sensor. Integrating the angular noise produces an angle estimate whose variance grows linearly with the integration interval – this is the classical angle random walk figure. In order to take advantage of the “mechanical” amplification afforded by a lightly damped resonance, CGV resonators with degenerate modal frequencies require feedback to equalize the response of the sensing degree of freedom due to angular rate inputs. Although the input and output noise sources can be considered to have constant spectral densities, noise-equivalent-rate spectrum typically exhibits a phase-lead characteristic in closed-loop CVGs. In this case, the variance of the integrated rate signal features both angle white noise and angle random walk trends. The

Allan variance is another common tool for capturing CVG performance, and it is shown how the angular noise spectra produce trends in the Allan variance graphs. A major issue in MEMS CVGs is the presence of fairly large zero-input measurement offsets. The magnitude of the offsets is driven by dissipation in the resonator so a direct means of reducing the offset is to fabricate the resonator from low-loss materials and mitigate so-called anchor loss, e.g., Trusov et al. (2011) and Prikhodko et al. (2011). Other approaches augment resonators with additional measurements that correlate with the long-term drift in the offset, e.g., Tatar et al. (2017) and Ge and M’Closkey (2017).

Singapore

Abstract

This article briefly discusses the topic of multi-agent consensus under imperfect communication channels including limited data rate, additive noises, and packet dropouts. The focus is on the design of encoders, decoders, and distributed control protocols so that the multi-agent system can reach consensus.

Keywords

Quantized consensus · Distributed control · Noisy communication channels

Introduction

Multi-agent consensus aims to reach an agreement of certain interested variables within a multi-agent system, where each agent is able to perform autonomous decision-making with sensing, computation, and communication capabilities. Posing as a fundamental problem in cooperative control of multi-agent systems, it has found wide applications in sensor networks, distributed estimation, formation control, smart grid, etc. Based on the communication with only local neighbors, distributed consensus protocols are much more preferable than centralized ones

due to its scalability with respect to the network size and robustness to the node or link failure. In practice, the communication is not perfect and several major issues need to be considered. In this survey, we will introduce the basics of multi-agent consensus under imperfect communication channels including limited data rate, packet dropouts, and additive channel noises. For the sake of an easy illustration, we shall focus on multi-agent systems with integrator dynamics.

To start with, let us briefly recall graph theory which has been an important tool for studying multi-agent systems. A graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is often used to model the interconnections of agents, where $\mathcal{V} = \{1, 2, \dots, N\}$ is the node set of N agents with $i \in \mathcal{V}$ representing the i -th agent; $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ denotes the edge set with each edge representing the information flow among agents. Throughout this survey, we consider the simple case that $\mathcal{G}$ is undirected, i.e., an edge $(j, i) \in \mathcal{E}$ implies that agent i and agent j can communicate with each other. The neighborhood set $\mathcal{N}_i$ of agent i is defined as $\mathcal{N}_i = \{j \neq i \mid (j, i) \in \mathcal{E}\}$. The adjacency weight matrix $\mathcal{A}$ is defined as $\mathcal{A} = [a_{ij}]_{N \times N}$, where $a_{ij} > 0$ iff $j \in \mathcal{N}_i$, and $a_{ij} = 0$ otherwise. The Laplacian matrix $\mathcal{L} = [\mathcal{L}_{ij}]_{N \times N}$ is defined as $\mathcal{L}_{ii} = \sum_{j \in \mathcal{N}_i} a_{ij}$, $\mathcal{L}_{ij} = -a_{ij}$ for $i \neq j$. Therefore, for undirected graphs, $\mathcal{L}$ is symmetric and $\mathcal{L}\mathbf{1} = \mathbf{1}'\mathcal{L} = \mathbf{0}$, where $\mathbf{1}$ is the vector of ones. Moreover, if $\mathcal{G}$ is undirected and connected, zero is a simple eigenvalue of $\mathcal{L}$, and all the other eigenvalues of $\mathcal{L}$ are positive, i.e.,

$$0 = \lambda_1 < \lambda_2 \leq \dots \leq \lambda_N,$$

where λ_i are eigenvalues of $\mathcal{L}$ sorted in an ascending order.

Suppose we have N agents with single integrator dynamics, i.e.,

$$\dot{x}_i(t) = u_i(t), \quad i = 1, \dots, N. \quad (1)$$

The consensus problem requires us to design distributed control inputs u_i , which relies on x_i and x_j , $j \in \mathcal{N}_i$ only, such that the agents can reach an agreement on the states asymptotically, as shown in the following definition.

Definition 1 The multi-agent system (1) achieves consensus if

$$\lim_{t \rightarrow \infty} \|x_i(t) - x_j(t)\| = 0, \quad \forall i, j = 1, \dots, N. \quad (2)$$

Moreover, if it holds that

$$\lim_{t \rightarrow \infty} \|x_i(t) - \frac{1}{N} \sum_{j=1}^N x_j(0)\| = 0, \quad i = 1, \dots, N \quad (3)$$

then average consensus is achieved.

A simple consensus protocol is the relative neighborhood state error-based consensus protocol, which is given by

$$\dot{u}_i(t) = a \sum_{j \in \mathcal{N}_i} a_{ij}(x_j(t) - x_i(t)), \quad (4)$$

where $a > 0$ is the consensus gain to be selected. With the consensus protocol (4), the stacked agent dynamics of $x = [x_1, \dots, x_N]'$ can be written as

$$\dot{x}(t) = (I - a\mathcal{L})x(t). \quad (5)$$

To show the average consensus with (4), note that we can decompose $x(0)$ as $x(0) = \frac{\mathbf{1}'x(0)}{N}\mathbf{1} + z$, where $\frac{\mathbf{1}'x(0)}{N}\mathbf{1}$ is the orthogonal projection of $x(0)$ onto the subspace spanned by $\mathbf{1}$ and z is orthogonal to $\mathbf{1}$. Moreover, if a is selected to satisfy $0 < a < \frac{2}{\lambda_N}$, $\mathbf{1}$ is a simple eigenvalue of $I - a\mathcal{L}$, and all the other eigenvalues of $I - a\mathcal{L}$ are within the unit circle. Besides, $(I - a\mathcal{L})\mathbf{1} = \mathbf{1}$. In view of the properties of $I - a\mathcal{L}$, we have from the iteration (5) that $\lim_{t \rightarrow \infty} x(t) = \frac{\mathbf{1}'x(0)}{N}\mathbf{1}$. As a result, average consensus is achieved.

However, the information of neighboring agents' states in the protocol (4) is typically obtained through communication. In practice, communication channels are inevitably subject to quantization error, noise, and uncertainty, especially in wireless communications. Thus, when there exists quantization error or noise in communication, the information obtained from

agent j by agent i can be expressed as

$$y_{ij}(t) = x_j(t) + w_{ij}(t); \quad (6)$$

when there exist packet dropouts, the information obtained from agent j by agent i can be expressed as

$$y_{ij}(t) = \gamma_{ij}(t)x_j(t), \quad (7)$$

where $\gamma_{ij}(t)$ is a 0-1 binary random variable.

Quantized Consensus

In a digital network, communication channels have a finite channel capacity, thus, at each time step, agents can only transmit a finite amount of information to their neighbors. Specifically, the sender needs to first encode the quantized state and then send out the code. When a neighbor receives the code, it uses a decoding algorithm to obtain an estimate of the sender's state. Hence, the multi-agent consensus problem needs to be

solved with quantized information and finite bits of data. The quantized consensus problem has been studied in the early works (Carli et al. 2007a; Kar and Moura 2009) where a uniform quantizer of infinite levels was used to design distributed control protocols. However, only consensus with bounded errors is achieved. Based on dynamic quantization, Carli et al. (2007b) achieved exact average consensus, but the number of quantization levels increases with the number of agents.

In Li et al. (2010), a distributed quantized consensus protocol was proposed for single integrator dynamics which can achieve exact average consensus with merely 1-bit information exchange between neighboring agents. This result relies on the specific design of both the encoder-decoder scheme and the distributed control protocol.

In the encoder-decoder scheme, dynamic quantization is applied to the state innovation to save communication cost. More specifically, the encoder Φ_j of the j -th agent is given by

$$\begin{cases} \xi_j(0) = 0, \\ \xi_j(t) = g(t-1)\Delta_j(t) + \xi_j(t-1), \\ \Delta_j(t) = Q\left[\frac{1}{g(t-1)}(x_j(t) - \xi_j(t-1))\right], t = 1, 2, \dots, \end{cases} \quad (8)$$

where $\xi_j(t)$ is the internal state of the encoder, $\Delta_j(t)$ is the output of the encoder to be sent to the neighbors of agent j , $g(t)$ is a positive scaling

function, and $Q(\cdot)$ is a finite-level uniform quantizer:

$$Q(y) = \begin{cases} 0, & -1/2 < y < 1/2; \\ i, & \frac{2i-1}{2} \leq y < \frac{2i+1}{2}, i = 1, 2, \dots, K-1; \\ K, & y \geq \frac{2K-1}{2}; \\ -Q(-y), & y \leq -1/2. \end{cases} \quad (9)$$

Although the above quantizer has $2K+1$ levels, there is no need to transmit the zero encoder output if the communication channel is assumed

to be perfect. Hence, the encoder output can be represented by at most $\lceil \log_2(2K) \rceil$ bits. Observe that the encoder Φ_j is based on the

innovation $x_j(t) - \xi_j(t-1)$ which generally requires fewer bits for its representation than the state $x_j(t)$.

For each communication channel $(j, i) \in \mathcal{E}$, agent i receives $\Delta_j(t)$ and uses the following decoder Ψ_{ij} to estimate x_j :

$$\begin{cases} y_{ij}(0) = 0, \\ y_{ij}(t) = g(t-1)\Delta_j(t) + y_{ij}(t-1), t = 1, 2, \dots, \end{cases} \quad (10)$$

where $y_{ij}(t)$ is an estimate of $x_j(t)$. Clearly, the decoded message $y_{ij}(t)$ is identical to the quantized state $\xi_j(t)$.

To achieve the exact consensus, the distributed control protocol is based on the self-compensation method to overcome information asymmetry of agents. For agent i , it is given by

$$u_i(t) = a \sum_{j \in \mathcal{N}_i} a_{ij}(y_{ij}(t) - \xi_i(t)). \quad (11)$$

Note that agent i does not use the exact state $x_i(t)$ to construct the control input. Instead, it uses the estimated state $\xi_i(t)$ obtained from its encoder output. This enables that both agents i and j use the same information for state estimation which is the key to achieving the exact consensus under the limited data rate.

Recall the error expression $w_{ij}(t) = y_{ij}(t) - x_j(t)$ in (6), and note that $y_{ij}(t) = \xi_j(t)$ for $j \in \mathcal{N}_i$. Thus, we can denote $w_j(t) = w_{ij}(t)$ for any $i \in \mathcal{N}_j$. Moreover, if we denote $\epsilon_j(t)$ as the quantization error, then we have $w_j(t) = g(t-1)\epsilon_j(t)$. Consequently, the dynamics of the closed loop system with the protocol (11) is given by

$$x(t+1) = (I - a\mathcal{L})x(t) - a\mathcal{L}w(t) \quad (12)$$

where $w = [w_1, \dots, w_N]' = g(t-1)[\epsilon_1, \dots, \epsilon_N]'$. Comparing with (5), it can be seen that (12) has an additional error term $-a\mathcal{L}w(t)$. Indeed, the scaling function $g(t)$ can be selected to be exponentially decaying, e.g., $g(t) = g_0\gamma^t$ with properly chosen $g_0 > 0$ and $\gamma \in (0, 1)$, and the quantization error can be guaranteed to be uniformly bounded. Therefore, the error term will be exponentially decaying, and under a connected and undirected network, it is shown that the

multi-agent system under the protocol (11) with encoder (8) and decoder (10) is able to achieve exact consensus with merely 1-bit of information exchange. Furthermore, the asymptotic convergence rate in relation to data rate and network synchronizability can be established – see Li et al. (2010) for more details.

With similar quantization techniques and distributed control protocol, the above work was extended to address more general topology (Zhang and Zhang 2013; Li et al. 2014). The cases of double and higher order integrator dynamics were studied in Li and Xie (2012) and Qiu et al. (2016) respectively, where only the first state variable is measurable, and the encoder-decoder scheme was designed to serve as a state observer. Specifically, it is shown that under a connected and undirected network and properly selected parameters, n bits of information exchange suffice to ensure the exponentially fast consensus for multi-agent systems with n -th order integrator dynamics. Qiu et al. (2017) considered the dynamics of $2m$ -th order oscillator, and it was found that the sufficient data rate for consensus is an integer between m and $2m$, depending on the position of the poles of the oscillator. The general LTI dynamics was also studied in You and Xie (2011a), and it was shown that the quantized consensus can be achieved with a limited data rate.

Average Consensus with Additive Noises

In analog communications, the additive communication noise channel model is often adopted, where the received information from agent j takes the form of (6). For simplicity, we assume that $w_{ij}(t)$ are zero mean white Gaussian noises

with variance σ_w^2 and $w_{ij}(t)$ are independent of each other for any i, j, t .

In this case, the consensus protocol is adapted to

$$u_i(t) = a(t) \sum_{j \in \mathcal{N}_i} a_{ij}(y_{ij}(t) - x_i(t)), \quad (13)$$

where a time-varying gain $a(t)$ is utilized and its necessity will be demonstrated soon.

The stacked dynamics can be computed as

$$x(t+1) = (I - a(t)\mathcal{L})x(t) + a(t)D_{\mathcal{G}}W(t), \quad (14)$$

where $D_{\mathcal{G}} = \text{diag}(\alpha_1, \dots, \alpha_N)$ with α_i being the i -th row of $\mathcal{A}$; $W(t) = [w_1^T(t), \dots, w_N^T(t)]^T$ with $w_i(t) = [w_{i1}(t), \dots, w_{iN}(t)]^T$.

It is clear that when there exist additive noises, exact consensus cannot be achieved. Therefore, we need a new definition of consensus, e.g., the commonly used mean square consensus definition.

Definition 2 The multi-agent system (1) achieves mean square consensus if

$$\lim_{t \rightarrow \infty} \mathbb{E}\{\| (I - \frac{1}{N}\mathbf{1}\mathbf{1}^T) x(t) \|^2\} = 0. \quad (15)$$

Moreover, if there exists a random variable x^* , with $\mathbb{E}\{x^*\} = \frac{1}{N} \sum_i x_i(0)$ and $\text{Var}(x^*) < \infty$, such that

$$\lim_{t \rightarrow \infty} \mathbb{E}\{\|x_i(t) - x^*\|^2\} = 0, \quad i = 1, \dots, N,$$

then the mean square average consensus is achieved.

Due to the additive noise in (14), the state $x(t)$ will fluctuate randomly. The fluctuation will not vanish as required by (15) if $a(t)$ does not converge to 0. Moreover, the convergence rate of $a(t)$ is critical for consensus. When $a(t)$ converges to 0 in (13), the signal $x_j(t)$ (contained in $y_{ij}(t)$) is attenuated together with the noise. Therefore, $a(t)$ cannot decrease too fast. Otherwise, the agents may converge to different individual limits.

It has been proved (Li and Zhang 2010) that the necessary and sufficient condition on $a(t)$ for the mean square consensus is

$$\sum_{t=0}^{\infty} a(t) = \infty, \quad \sum_{t=0}^{\infty} a(t)^2 < \infty. \quad (16)$$

Below we will briefly outline the proof. Since

$$\begin{aligned} \frac{1}{N} \sum_i x_i(t+1) &= \frac{1}{N} \sum_i x_i(t) \\ &\quad + \frac{1}{N} \mathbf{1}^T D_{\mathcal{G}} a(t) W(t), \end{aligned}$$

that is

$$\begin{aligned} \frac{1}{N} \sum_i x_i(t) &= \frac{1}{N} \sum_i x_i(0) \\ &\quad + \frac{1}{N} \mathbf{1}^T D_{\mathcal{G}} \sum_{i=0}^{t-1} a(i) W(i), \end{aligned}$$

we can expect that each agent's state would converge to

$$\begin{aligned} x^* &= \frac{1}{N} \sum_i x_i(0) \\ &\quad + \frac{1}{N} \mathbf{1}^T D_{\mathcal{G}} \sum_{t=0}^{\infty} a(t) W(t), \end{aligned}$$

which has bounded variance if and only if

$$\sum_{t=0}^{\infty} a(t)^2 < \infty. \quad (17)$$

Moreover, let $\delta(t) = (I - \frac{1}{N}\mathbf{1}\mathbf{1}^T)x(t)$ and define the Lyapunov function $V(t) = \delta(t)'\delta(t)$, with some manipulations; we can show that there exist t_0 and positive constants c_1, c_2 , and c_3 , such that for $t > t_0$,

$$\begin{aligned} (1 - c_1 a(t)) \mathbb{E}\{V(t)\} + c_2 a(t)^2 &\geq \mathbb{E}\{V(t+1)\} \\ &\geq e^{-c_3 \sum_{t=t_0}^{\infty} a(t)} \mathbb{E}\{V(t_0)\}. \end{aligned}$$

Therefore, a necessary and sufficient condition to ensure $\lim_{t \rightarrow \infty} \mathbb{E}\{V(t)\} = 0$ is

$$\sum_{t=0}^{\infty} a(t) = \infty, \quad \lim_{t \rightarrow \infty} a(t) = 0,$$

which, together with (17), yields the gain condition (16).

As is clear from the above proof, $\sum_{t=0}^{\infty} a(t) = \infty$ is the convergence condition, which is to make all agents' states reach an agreement with a proper rate. On the other hand, $\sum_{t=0}^{\infty} a(t)^2 < \infty$ is the robustness condition, which is to attenuate the measurement noises, such that the consensus protocol is robust with respect to measurement noises.

The gain condition (16) has been shown to be sufficient in various settings: e.g., double integrator dynamics (Cheng et al. 2011), general LTI agent dynamics (Cheng et al. 2014), time-varying topology (Huang et al. 2010; Huang and Manton 2010; Li and Zhang 2010), and output feedback case (Wang et al. 2015). The convergence rate analysis has also been studied (Xu et al. 2012; Tang and Li 2015; Cheng et al. 2016).

Packet Dropouts

In the presence of packet dropouts, the received information from agent j takes the form of (7). Accordingly, the consensus protocol is adapted to

$$u_i(t) = a \sum_{j \in \mathcal{N}_i} a_{ij} \gamma_{ij}(t) (x_j(t) - x_i(t)). \quad (18)$$

Clearly, it implies that only when $\gamma_{ij}(t) = 1$, then the relative state between agent j and agent i will be used. Consequently, the stacked dynamics is given by

$$x(t+1) = (I - a\mathcal{L}(t))x(t), \quad (19)$$

where $\mathcal{L}(t) = [\mathcal{L}_{ij}(t)]_{N \times N}$ is defined as $\mathcal{L}_{ii}(t) = \sum_{j \in \mathcal{N}_i} a_{ij} \gamma_{ij}(t)$, $\mathcal{L}_{ij} = -a_{ij} \gamma_{ij}(t)$ for $i \neq j$. It was shown in (Tahbaz-Salehi and Jadbabaie 2008) that almost sure consensus can be achieved if the spectrum of the expected graph is smaller than 1, i.e., $|\lambda_2(E(I - \mathcal{L}(t)))| < 1$.

More research works have been conducted by modeling $\gamma_{ij}(t)$ as a Bernoulli process with $P(\gamma_{ij}(t) = 1) = p_{ij}$ which is the recovery rate on the communication channel (i, j) . It is found that the recovery rate plays an important role in ensuring consensus. In Zhang and Tian (2012) and You et al. (2013), it was shown that the recovery rate needs to be sufficiently large to ensure the mean square consensus.

Furthermore, it is also worth mentioning that when $\gamma_{ij}(t)$ is a general random variable, then the problem is closely related with the fading channel issue. See the recent works (Xu et al. 2016, 2018) for more details.

Summary and Future Research

This article described the multi-agent consensus under noisy environment with special focus on consensus where communication channels are of limited data rate or subject to additive/multiplicative noises. While the consensus problem has been extensively studied, there are several issues that remain to be further studied.

For the quantized consensus problem, most of the existing studies have been limited to integrator dynamics with a few exceptions; see e.g., You and Xie (2011b), where a lower bound on the required data rate for consensus is provided. The bound, however, is overly conservative for general dynamics. It is of interest to study the minimal data rate problem for consensus of general linear dynamics. On the other hand, Li et al. (2010) established a relationship between the asymptotic ($N \rightarrow \infty$) consensus convergence rate and network synchronizability (λ_2/λ_N). Similar convergence rate result is not available for higher order integrator dynamics. Moreover, (You and Xie 2011b) has provided a necessary and sufficient condition for consensusability in terms of the agent dynamics and network topology under the assumption that the communication channels have infinite capacities. It is interesting to further take data rate into consideration from both theoretical and practical points of view though the problem is challenging.

Nominal Model-Predictive Control

Lars Grüne

Mathematical Institute, University of Bayreuth, Bayreuth, Germany

Abstract

Model-predictive control is a controller design method which synthesizes a sampled data feedback controller from the iterative solution of open-loop optimal control problems. We describe the basic functionality of

MPC controllers, their properties regarding feasibility, stability and performance, and the assumptions needed in order to rigorously ensure these properties in a nominal setting.

Keywords

Model predictive control · Receding horizon control · Piecewise optimal control

Introduction

Model-predictive control (MPC) is a method for the optimization-based control of linear and nonlinear dynamical systems. While the literal meaning of “model-predictive control” applies to virtually every model-based controller design method, nowadays the term commonly refers to control methods in which pieces of open-loop optimal control functions or sequences are put together in order to synthesize a sampled data feedback law. As such, it is often used synonymously with “receding horizon control.”

The concept of MPC was first presented in Propöř (1963) and was reinvented several times already in the 1960s. Due to the lack of sufficiently fast computer hardware, for a while these ideas did not have much of an impact. This changed during the 1970s when MPC was successfully used in chemical process control. At that time, MPC was mainly applied to linear systems with quadratic cost and linear constraints, since for this class of problems algorithms were sufficiently fast for real-time implementation – at least for the typically relatively slow dynamics of process control systems. The 1980s have then seen the development of theory and increasingly sophisticated concepts for linear MPC, while in the 1990s nonlinear MPC (often abbreviated as NMPC) attracted the attention of the MPC community. After the year 2000, several gaps in the analysis of nonlinear MPC without terminal constraints and costs were closed, and increasingly faster algorithms were developed. Together with the progress in hardware, this has considerably broadened the possible applications of both linear and nonlinear MPC.

In this entry, we explain the functionality of nominal MPC along with its most important properties and the assumptions needed to rigorously ensure these properties. We also give some hints on the underlying proofs. The term nominal MPC refers to the assumption that the mismatch between our model and the real plant is sufficiently small to be neglected in the following considerations. If this is not the case, methods from robust MPC must be used (► [Robust Model Predictive Control](#)). We describe all concepts for nonlinear discrete time systems, noting that the basic results outlined in this entry are conceptually similar for linear and for continuous-time systems.

Model-Predictive Control

In this entry, we discuss MPC for discrete time control systems of the form

$$x_{\mathbf{u}}(j+1) = f(x_{\mathbf{u}}(j), u(j)), \quad x_{\mathbf{u}}(0) = x_0 \quad (1)$$

with state $x_{\mathbf{u}}(j) \in X$, initial condition $x_0 \in \mathbb{X}$, and control input sequence $\mathbf{u} = (u(0), u(1), \dots)$ with $u(k) \in U$, where the state space X and the control value space U are normed spaces. For control systems in continuous time, one may either apply the discrete time approach to a sampled data model of the system. Alternatively, continuous-time versions of the concepts and results from this entry are available in the literature; see, e.g., Findeisen and Allgöwer (2002) or Mayne et al. (2000).

The core of any MPC scheme is an optimal control problem of the form

$$\text{minimize } J_N(x_0, \mathbf{u}) \quad (2)$$

w.r.t. $\mathbf{u} = (u(0), \dots, u(N-1))$ with

$$J_N(x_0, \mathbf{u}) : \sum_{j=0}^{N-1} \ell(x_{\mathbf{u}}(j), u(j)) + F(x_{\mathbf{u}}(N)) \quad (3)$$

subject to the constraints

$$\begin{aligned} u(j) \in \mathbb{U}, x_{\mathbf{u}}(j) \in \mathbb{X} \text{ for } j = 0, \dots, N-1 \\ x_{\mathbf{u}}(N) \in \mathbb{X}_0, \end{aligned} \quad (4)$$

for control constraint set $\mathbb{U} \subseteq U$, state constraint set $\mathbb{X} \subseteq X$, and terminal constraint set $\mathbb{X}_0 \subseteq X$. The function $\ell : \mathbb{X} \times \mathbb{U} \rightarrow \mathbb{R}$ is called stage cost or running cost; the function $F : \mathbb{X} \rightarrow \mathbb{R}$ is referred to as terminal cost. We assume that for each initial value $x_0 \in \mathbb{X}$, the optimal control problem (2) has a solution and denote the corresponding minimizing control sequence by $\mathbf{u}^*$. Algorithms for computing $\mathbf{u}^*$ are discussed in ► [Optimization Algorithms for MPC](#) and ► [Explicit Model Predictive Control](#).

The key idea of MPC is to compute the values $\mu_N(x)$ of the MPC feedback law μ_N from the open-loop optimal control sequences $\mathbf{u}^*$. To formalize this idea, consider the closed-loop system

$$x_{\mu_N}(k+1) = f(x_{\mu_N}(k), \mu_N(x_{\mu_N}(k))). \quad (5)$$

In order to evaluate μ_N along the closed-loop solution, given an initial value $x_{\mu_N}(0) \in \mathbb{X}$, we iteratively perform the following steps.

Basic MPC Loop

1. Set $k := 0$.
2. Solve (2)–(4) for $x_0 = x_{\mu_N}(k)$; denote the optimal control sequence by $\mathbf{u}^* = (u^*(0), \dots, u^*(N-1))$.
3. Set $\mu_N(x_{\mu_N}(k)) : u^*(0)$, compute $x_{\mu_N}(k+1)$ according to (5), set $k := k+1$ and go to (1).

Due to its ability to handle constraints and possibly nonlinear dynamics, MPC has become one of the most popular modern control methods in the industry (► [Model Predictive Control in Practice](#)). While in the literature various variants of this basic scheme are discussed, here we restrict ourselves to this most widely used basic MPC scheme.

When analyzing an MPC scheme, three properties are important:

- **Recursive Feasibility**, i.e., the property that the constraints (4) can be satisfied in Step (ii) in each sampling instant
- **Stability**, i.e., in particular convergence of the closed-loop solutions $x_{\mu_N}(k)$ to a desired equilibrium x_* as $k \rightarrow \infty$
- **Performance**, i.e., appropriate quantitative properties of $x_{\mu_N}(k)$

Here we discuss these three issues for two widely used MPC variants:

1. MPC with terminal constraints and costs
2. MPC with neither terminal constraints nor costs

In (a), F and $\mathbb{X}_0$ in (3) and (4) are specifically designed in order to guarantee proper performance of the closed loop. In (b), we set $F \equiv 0$ and $\mathbb{X}_0 = \mathbb{X}$. Thus, the choice of ℓ and N in (3) is the most important part of the design procedure.

Recursive Feasibility

Since the ability to handle constraints is one of the key features of MPC, it is important to ensure that the constraints $x_{\mu_N}(k) \in \mathbb{X}$ and $\mu_N(x_{\mu_N}(k)) \in \mathbb{U}$ are satisfied for all $k \geq 0$. However, beyond constraint satisfaction, the stronger property $x_{\mu_N}(k) \in \mathbb{X}_N$ is required, where $\mathbb{X}_N$ denotes the *feasible set* for horizon N ,

$$\mathbb{X}_N := \{x \in \mathbb{X} \mid \text{there exists } \mathbf{u} \text{ such that (4) holds}\}.$$

The property $x \in \mathbb{X}_N$ is called *feasibility* of x . Feasibility of $x = x_{\mu_N}(k)$ is a prerequisite for the MPC feedback μ_N being well defined, because the nonexistence of such an admissible control sequence $\mathbf{u}$ would imply that solving (2) under the constraints (4) in Step (ii) of the MPC iteration is impossible.

Since for $k \geq 0$ the state $x_{\mu_N}(k+1) = f(x_{\mu_N}(k), u^*(0))$ is determined by the solution of the previous optimal control problem, the usual way to address this problem is via the notion of

recursive feasibility. This property demands the existence of a set $A \subseteq \mathbb{X}$ such that:

- For each $x_0 \in A$, the problem (2)–(4) is feasible.
- For each $x_0 \in A$ and the optimal control u^* from (2) to (4), the relation $f(x_0, u^*(0)) \in A$ holds.

It is not too difficult to see that this property implies $x_{\mu_N}(k) \in A$ for all $k \geq 1$ if $x_{\mu_N}(0) \in A$.

For terminal-constrained problems, recursive feasibility is usually established by demanding that the terminal constraint set $\mathbb{X}_0$ is *viable* or *controlled forward invariant*. This means that for each $x \in \mathbb{X}_0$, there exists $u \in \mathbb{U}$ with $f(x, u) \in \mathbb{X}_0$. Under this assumption, it is quite straightforward to prove that the feasible set $A = \mathbb{X}_N$ is also recursively feasible (Grüne and Pannek 2011, Lemma 5.11). Note that viability of $\mathbb{X}_0$ is immediate if $\mathbb{X}_0 = \{x_*\}$ and $x_* \in \mathbb{X}$ is an equilibrium, i.e., a point for which there exists $u_* \in \mathbb{U}$ with $f(x_*, u_*) = x_*$. This setting is referred to as *equilibrium terminal constraint*.

For MPC without terminal constraints, the most straightforward way to ensure recursive feasibility is to assume that the state constraint set $\mathbb{X}$ is viable (Grüne and Pannek 2011, Theorem 3.5). However, checking viability and even more constructing a viable state constraint set is in general a very difficult task. Hence, other methods for establishing recursive feasibility are needed. One method is to assume that the sequence of feasible sets $\mathbb{X}_N$, $N \in \mathbb{N}$ becomes *stationary* for some N_0 , i.e., that $\mathbb{X}_{N+1} = \mathbb{X}_N$ holds for all $N \geq N_0$. Under this assumption, recursive feasibility of $\mathbb{X}_{N_0}$ follows, see Kerrigan (2000, Theorem 5.3). However, like viability, stationarity is difficult to verify.

For this reason, a conceptually different approach to ensure recursive feasibility was presented in Grüne and Pannek (2011, Theorem 7.20); a similar approach for linear systems can be found in Primbs and Nevistić (2000). The approach is suitable for stabilizing MPC problems in which the stage cost ℓ penalizes the distance to a desired equilibrium x_* (cf. section “Stability”). Assuming the existence – but not

the knowledge – of a viable neighborhood $\mathcal{N}$ of x_* , one can show that any initial point x_0 for which the corresponding open-loop optimal solution satisfies $x_{u^*}(j) \in \mathcal{N}$ or some $j \leq N$ is contained in a recursively feasible set. The fact that ℓ penalizes the distance to x_* then implies $x_{u^*}(j) \in \mathcal{N}$ for suitable initial values. Together, these properties yield the existence of recursively feasible sets A_N which converge to set A_∞ as N increases.

Stability

Stability in the sense of this entry refers to the fact that a prespecified equilibrium $x_* \in \mathbb{X}$ – typically a desired operating point – is asymptotically stable for the MPC closed loop for all initial values in some set $\mathcal{S}$. This means that the solutions $x_{\mu_N}(k)$ starting in $\mathcal{S}$ converge to x_* as $k \rightarrow \infty$ and that solutions starting close to x_* remain close to x_* for all $k \geq 0$. Note that this setting can be extended to time-varying reference solutions; see ► [Tracking Model Predictive Control](#).

In order to enforce this property, we assume that the stage cost ℓ penalizes the distance to the equilibrium x_* in the following sense: ℓ satisfies

$$\ell(x_*, u_*) = 0 \text{ and } \alpha_1(|x|) \leq \ell(x, u) \quad (6)$$

for all $x \in \mathbb{X}$ and $u \in \mathbb{U}$. Here α_1 is a $\mathcal{K}_\infty$ function, i.e., a continuous function $\alpha_1 : [0, \infty) \rightarrow [0, \infty)$ which is strictly increasing, unbounded, and satisfies $\alpha_1(0) = 0$. With $|x|$, we denote the norm on X . In this entry, we exclusively discuss stage costs ℓ satisfying (6). More general settings using appropriate detectability conditions are discussed in Rawlings and Mayne (2009, Sect. 2.7) or Grimm et al. (2005) in the context of stabilizing MPC. Even more general ℓ are allowed in the context of economic MPC; see the ► [Economic Model Predictive Control](#) article.

In case of terminal constraints and terminal costs, a compatibility condition between ℓ and F is needed on $\mathbb{X}_0$ in order to ensure stability. More precisely, we demand that for each $x \in \mathbb{X}_0$ there exists a control value $u \in \mathbb{U}$ such that $f(x, u) \in \mathbb{X}_0$ and

$$F(f(x, u)) - F(x) \leq -\ell(x, u) \quad (7)$$

holds. Observe that the condition $f(x, u) \in \mathbb{X}_0$ is again the viability condition which we already imposed for ensuring recursive feasibility. Note that (7) is trivially satisfied for $F \equiv 0$ in case of $\mathbb{X}_0 = \{x_*\}$ by choosing $u = u_*$.

Stability is now concluded by using the optimal value function

$$V_N(x_0) := \inf_{\mathbf{u} \text{ s.t. (4)}} J_N(x_0, \mathbf{u})$$

as a Lyapunov function. This will yield stability on $\mathcal{S} = \mathbb{X}_N$, as $\mathbb{X}_N$ is exactly the set on which V_N is defined. In order to prove that V_N is a Lyapunov function, we need to check that V_N is bounded from below and above by $\mathcal{K}_\infty$ functions α_1 and α_2 and that V_N is strictly decaying along the closed-loop solution.

The first amounts to checking

$$\alpha_1(|x|) \leq V_N(x) \leq \alpha_2(|x|) \quad (8)$$

for all $x \in \mathbb{X}_N$. The lower bound follows immediately from (6) (with the same α_1), and the upper bound can be ensured by conditions on the problem data (see, e.g., Rawlings and Mayne 2009, Sect. 4.5; Grüne and Pannek 2011, Sect. 5.3).

For ensuring that V_N is strictly decreasing along the closed-loop solutions, we need to prove

$$V_N(f(x, \mu_N(x))) \leq V_N(x) - \ell(x, \mu_N(x)). \quad (9)$$

In order to prove this inequality, one uses on the one hand the dynamic programming principle stating that

$$V_{N-1}(f(x, \mu_N(x))) = V_N(x_0) - \ell(x, \mu_N(x)). \quad (10)$$

On the other hand, one shows that (7) implies

$$V_{N-1}(x) \geq V_N(x) \quad (11)$$

for all $x \in \mathbb{X}_N$. Inserting (11) with $f(x, \mu_N(x))$ in place of x into (10) then immediately yields (9). Details of this proof can be found, e.g., in Mayne et al. (2000), Rawlings and Mayne

(2009), or Grüne and Pannek (2011). The survey Mayne et al. (2000) is probably the first paper which develops the conditions needed for this proof in a systematic way; a continuous-time version of these results can be found in Fontes (2001).

Summarizing, for MPC with terminal constraints and costs, under the conditions (6)–(8), we obtain asymptotic stability of x_* on $\mathcal{S} = \mathbb{X}_N$.

For MPC without terminal constraints and costs, i.e., with $\mathbb{X}_0 = \mathbb{X}$ and $F \equiv 0$, these conditions can never be satisfied, as (7) will immediately imply $\ell(x, u) = 0$ for all $x \in \mathbb{X}$, contradicting (6). Moreover, without terminal constraints and costs, one cannot expect (9) to be true. This is because without terminal constraints, the inequality $V_{N-1}(x) \leq V_N(x)$ holds, which together with the dynamic programming principle implies that if (9) holds, then it holds with equality. This, however, would imply that μ_N is the infinite horizon optimal feedback law, which – though not impossible – is very unlikely to hold.

Thus, we need to relax (9). In order to do so, instead of (9), we assume the relaxed inequality

$$V_N(f(x, \mu_N(x))) \leq V_N(x) - \alpha \ell(x, \mu_N(x)) \quad (12)$$

for some $\alpha > 0$ and all $x \in \mathbb{X}$, which is still enough to conclude asymptotic stability of x_* if (6) and (8) hold. The existence of such an α can be concluded from bounds on the optimal value function V_N . Assuming the existence of constants $\gamma_K \geq 0$ such that the inequality

$$V_K(x) \leq \gamma_K \min_{u \in \mathbb{U}} \ell(x, u) \quad (13)$$

holds for all $K = 1, \dots, N$ and $x \in \mathbb{X}$, there are various ways to compute α from $\gamma_1, \dots, \gamma_N$, see Grüne (2012, Sect. 3). The best possible estimate for α , whose derivation is explained in detail in Grüne and Pannek (2011, Chap. 6), yields

$$\alpha = 1 - \frac{(\gamma_N - 1) \prod_{i=2}^N (\gamma_i - 1)}{\prod_{i=2}^N \gamma_i - \prod_{i=2}^N (\gamma_i - 1)}. \quad (14)$$

Though not immediately obvious, a closer look at this term reveals $\alpha \rightarrow 1$ as $N \rightarrow \infty$ if the γ_K are bounded. Hence, $\alpha > 0$ for sufficiently large N .

Summarizing the second part of this section, for MPC without terminal constraints and costs, under the conditions (6), (8), and (13), asymptotic stability follows on $\mathcal{S} = \mathbb{X}$ for all optimization horizons N for which $\alpha > 0$ holds in (14). Note that the condition (13) implicitly depends on the choice of ℓ . A judicious choice of ℓ can considerably reduce the size of the horizon N for which $\alpha > 0$ holds, see Grüne and Pannek (2011, Sect. 6.6) and thus the computational effort for solving (2)–(4).

Performance

Performance of MPC controllers can be measured in many different ways. As the MPC controller is derived from successive solutions of (2), a natural quantitative way to measure its performance is to evaluate the infinite horizon functional corresponding to (3) along the closed loop, i.e.,

$$J_{\infty}^{\ell}(x_0, \mu_N) := \sum_{k=0}^{\infty} \ell(x_{\mu_N}(k), \mu_N(x_{\mu_N}(k)))$$

with $x_{\mu_N}(0) = x_0$. This value can then be compared with the optimal infinite horizon value

$$V_{\infty}(x_0) := \inf_{\mathbf{u}: u(k) \in \mathbb{U}, x_{\mathbf{u}}(k) \in \mathbb{X}} J_{\infty}(x_0, \mathbf{u})$$

where

$$J_{\infty}(x_0, \mathbf{u}) := \sum_{k=0}^{\infty} \ell(x_{\mathbf{u}}(k), u(k)).$$

To this end, for MPC with terminal constraints and costs, by induction over (9) and using non-negativity of ℓ , it is fairly easy to conclude the inequality

$$J_{\infty}^{\ell}(x_0, \mu_N) \leq V_N(x_0)$$

for all $x \in \mathbb{X}_N$. However, due to the conditions on the terminal cost in (7), V_N may be considerably larger than V_{∞} and an estimate relating these two functions is in general not easy to derive (Grüne and Pannek 2011, Examples 5.18 and 5.19). However, it is possible to show that under the same assumptions guaranteeing stability, the convergence

$$V_N(x) \rightarrow V_{\infty}(x)$$

holds for $N \rightarrow \infty$ (Grüne and Pannek 2011, Theorem 5.21). Hence, we recover approximately optimal infinite horizon performance for sufficiently large horizon N .

For MPC without terminal constraints and costs, the inequality $V_N(x_0) \leq V_{\infty}(x_0)$ is immediate; however, (9) will typically not hold. As a remedy, we can use (12) in order to derive an estimate. Using induction over (12), we arrive at the estimate

$$J_{\infty}^{\ell}(x_0, \mu_N) \leq V_N(x_0)/\alpha \leq V_{\infty}(x_0)/\alpha.$$

Since $\alpha \rightarrow 1$ as $N \rightarrow \infty$, also in this case we obtain approximately optimal infinite horizon performance for sufficiently large horizon N .

Summary and Future Directions

MPC is a controller design method which uses the iterative solution of open-loop optimal control problems in order to synthesize a sampled data feedback controller μ_N . The advantages of MPC are its ability to handle constraints, the rigorously provable stability properties of the closed loop, and its approximate optimality properties. Assumptions needed in order to rigorously ensure these properties together with the corresponding mathematical arguments have been outlined in this entry, both for MPC with terminal constraints and costs and without. Among the disadvantages of MPC are the computational effort and the fact that the resulting feedback is a full state feedback, thus necessitating the use of a state estimator to reconstruct the state from output data (► [Moving Horizon Estimation](#)).

Future directions include the application of MPC to more general problems than set point stabilization or tracking, the development of efficient algorithms for large-scale problems including those originating from discretized infinite-dimensional control problems, and the understanding of the opportunities and limitations of MPC in increasingly complex environments; see also ► [Distributed Model Predictive Control](#).

Nonlinear Adaptive Control

Alessandro Astolfi

Department of Electrical and Electronic Engineering, Imperial College London, London, UK

Dipartimento di Ingegneria Civile e Ingegneria Informatica, Università di Roma Tor Vergata, Rome, Italy

Abstract

We consider the control of nonlinear systems in which parameters are uncertain and may vary. For such systems the control must adapt to the parameter change to deliver closed-loop performance, such as asymptotic stability or tracking. A concise description of available methods and basic adaptive stabilization results, which can be used as building blocks for complex adaptive control problems, are discussed.

Keywords

Adaptive control · Nonlinear systems · Adaptive stabilization · Estimation ·

Stability · Certainty equivalence · Output feedback

Introduction

The adaptive control problem, namely, the problem of designing a feedback controller which contains an *adaptation mechanism* to counteract changes in the parameters of the system to be controlled, is of significant importance in applications. In almost all systems, physical parameters are subject to changes. These may be triggered, for example, by changes in temperature (the volume of a liquid/gas), aging (the friction coefficient of a mechanical system), or normal operation (the mass of the fuel of an aircraft changes during flight; the center of mass of a vehicle is affected by its load).

While adaptive control is naturally associated with the notion of estimation – the parameters of a system have to be identified to design a controller – it may be possible to design adaptive controllers which do not rely on an *explicit* parameter estimation – it is sufficient to estimate the *role* of the parameters in the control signal.

Adaptive control is different from robust control. In the simplest possible scenario, the aim of robust control is to design a control law guaranteeing performance specifications for a given range of parameter values. Robust control thus requires some a priori information on the parameter. Adaptive control does not require any a priori information on the parameter, although any such information can be exploited in the controller design, but requires a parameterized model: a model which contains information on the way the parameters affect the dynamics of the system.

The adaptive control problem for general nonlinear systems can be formulated as follows. Consider a nonlinear system described by equations of the form (while we focus on continuous-time systems, similar considerations apply to discrete-time systems):

$$\dot{x} = F(x, u, \theta), \quad y = H(x, \theta), \quad (1)$$

where $x(t) \in \mathbb{R}^n$ denotes the state of the system, $u(t) \in \mathbb{R}^m$ denotes the input of the system,

$\theta \in \mathbb{R}^q$ denotes the constant unknown parameter, $y(t) \in \mathbb{R}^p$ denotes the measured output, and $F : \mathbb{R}^n \times \mathbb{R}^m \times \mathbb{R}^q \rightarrow \mathbb{R}^n$ and $H : \mathbb{R}^n \times \mathbb{R}^q \rightarrow \mathbb{R}^p$ are smooth mappings. In what follows, for simplicity, we mostly assume that $y = x$, that is, the whole state of the system is available for control design.

The adaptive control problem consists in finding, if possible, a dynamic control law described by equations of the form

$$\dot{\hat{\theta}} = w(x, \hat{\theta}, r), \quad (2)$$

$$u = v(x, \hat{\theta}, r), \quad (3)$$

with $r(t) \in \mathbb{R}^s$ an exogenous (reference) signal, and $w : \mathbb{R}^n \times \mathbb{R}^q \times \mathbb{R}^s \rightarrow \mathbb{R}^q$ and $v : \mathbb{R}^n \times \mathbb{R}^q \times \mathbb{R}^s \rightarrow \mathbb{R}^m$ smooth mappings, such that the closed-loop system, described by the equations

$$\dot{x} = F(x, v(x, \hat{\theta}, r), \theta), \quad \dot{\hat{\theta}} = w(x, \hat{\theta}, r), \quad (4)$$

has specific properties. For example one could require that all trajectories be bounded and the x -component of the state converge to a given value x^* (this is the so-called adaptive regulation requirement) or that the input-output behavior of the system from the input r to some user-defined output signal coincide with a given reference model (this is the so-called model reference adaptive control requirement).

A natural way to characterize design specifications for the adaptive control problem and to facilitate its solution is to assume the existence of a known parameter controller, described by the equation

$$u = v^*(x, \theta, r), \quad (5)$$

such that the nonadaptive closed-loop system $\dot{x} = F(x, v^*(x, \theta, r), \theta)$ satisfies given design specifications. In this perspective, the adaptive control problem boils down to the design of the *update law* (2) and of the *feedback law* (3) such that the behavior of the adaptive closed-loop system *matches* that of the nonadaptive closed-loop system $\dot{x} = F(x, v^*(x, \theta, r), \theta)$.

The above description suggests a design method for the *feedback law*: one could replace θ with $\hat{\theta}$ in Eq. (5). This design is often known

as certainty equivalence design and lends itself to the interpretation that $\hat{\theta}$ be an estimate for θ . Naturally, one could also modify the feedback law, adding further $\hat{\theta}$ -dependent and x -dependent terms: this is often called a redesign. Redesign may be guided by various considerations, for example, it may be based on the use of a specific Lyapunov function (yielding the so-called Lyapunov redesign), or by structural properties of the system, or by robustness constraints.

The interpretation of $\hat{\theta}$ as an estimate for θ leads to two somewhat diverse approaches for the design of the update law. The former, pursued in the so-called estimation-based (or indirect) adaptive control, relies on the design of a parameter estimator, for example, using recursive least-square methods. This approach has its roots in identification theory and has been studied in-depth for linear systems. The latter relies on the observation that the design of an update law is equivalent to the design of a (reduced-order) observer for the extended system

$$\dot{x} = F(x, u, \theta), \quad \dot{\theta} = 0,$$

with output $y = x$. This approach has its roots in the theory of nonlinear observer design.

The approaches described so far rely on a sort of separation principle: the update law and the feedback law are designed separately. While this approach may be adequate for linear systems, for nonlinear systems it is often necessary to design the update law and the feedback law in one step, i.e., the selection of the feedback law depends upon the selection of the update law and vice versa. To illustrate this design method and provide some explicit adaptive control design tools, we focus on a special class of nonlinear systems: systems which are linearly parameterized in the unknown parameter.

Linearly Parameterized Systems

Consider the system (1) and assume that the mapping F is affine in the parameter θ and in the control u , namely:

$$F(x, u, \theta) = f_0(x) + g(x)u + f_1(x)\theta, \quad (6)$$

with $f_0 : \mathbb{R}^n \rightarrow \mathbb{R}^n$, $g : \mathbb{R}^n \rightarrow \mathbb{R}^n \times \mathbb{R}^m$, and $f_1 : \mathbb{R}^n \rightarrow \mathbb{R}^n \times \mathbb{R}^q$ smooth mappings. For this class of systems, under additional assumptions, it is possible to provide systematic adaptive control design tools. We provide two formal results: additional results (depending on the specific assumptions imposed on the system) may be derived. In both cases the focus is on the adaptive stabilization problem: the goal of the adaptive controller is to render a given equilibrium stable, in the sense of Lyapunov, and to guarantee convergence of the x -component of the state (recall that the state of the adaptive closed-loop system is the vector $(x, \hat{\theta})$).

Theorem 1 Consider the system (6) and a point x^* . Assume there exist a known parameter controller

$$u = v_0(x) + v_1(x)\theta,$$

with $v_0 : \mathbb{R}^n \rightarrow \mathbb{R}^m$ and $v_1 : \mathbb{R}^n \rightarrow \mathbb{R}^m \times \mathbb{R}^q$ smooth mappings, and a positive definite and radially unbounded function $V : \mathbb{R}^n \rightarrow \mathbb{R}$, such that $V(x^*) = 0$ and

$$\frac{\partial V}{\partial x} f^*(x, \theta) < 0$$

for all $x \neq x^*$, where $f^*(x, \theta) = f_0(x) + g(x)(v_0(x) + v_1(x)\theta) + f_1(x)\theta$.

Then the update law

$$\dot{\hat{\theta}} = - \left(\frac{\partial V}{\partial x} g(x) v_1(x) \right)^\top$$

and the feedback law

$$u = v_0(x) + v_1(x)\hat{\theta}$$

are such that all trajectories of the closed-loop system are bounded and $\lim_{t \rightarrow \infty} x(t) = x^*$.

Theorem 2 Consider the system (6) and a point x^* . Assume there exists a known parameter controller $u = v(x, \theta)$ such that the closed-loop system

$$\dot{x} = f^*(x, \theta),$$

where $f^*(x, \theta) = f_0(x) + g(x)v(x, \theta) + f_1(x)\theta$, has a globally asymptotically stable equilibrium at x^* . Assume, in addition, that there exists a mapping $\beta : \mathbb{R}^n \rightarrow \mathbb{R}^q$ such that all trajectories of the system

$$\begin{aligned}\dot{z} &= -\left[\frac{\partial \beta}{\partial x} f_1(x)\right] z, \\ \dot{x} &= f^*(x) + g(x)(v(x, \theta + z) - v(x, \theta))\end{aligned}\quad (7)$$

are bounded and satisfy

$$\lim_{t \rightarrow \infty} [g(x(t))(v(x(t), \theta + z(t)) - v(x(t), \theta))] = 0.$$

Then the update law

$$\begin{aligned}\dot{\hat{\theta}} &= -\frac{\partial \beta}{\partial x} \left[f_0(x) + f_1(x)(\hat{\theta} + \beta(x)) \right. \\ &\quad \left. + g(x)v(x, \hat{\theta} + \beta(x)) \right]\end{aligned}$$

and the feedback law

$$u = v(x, \hat{\theta} + \beta(x))$$

are such that all trajectories of the closed-loop system are bounded and $\lim_{t \rightarrow \infty} x(t) = x^*$.

The stability properties of the adaptive closed-loop system in Theorem 1 can be studied with the Lyapunov function $W(x, \hat{\theta}) = V(x) + \frac{1}{2}\|\hat{\theta} - \theta\|^2$, whereas a Lyapunov analysis for the adaptive closed-loop system in Theorem 2 can be carried out, under additional assumptions, via a Lyapunov function of the form $W(x, \hat{\theta}) = V(x) + \frac{1}{2}\|\hat{\theta} - \theta + \beta(x)\|^2$. This suggests that in Theorem 1 $\hat{\theta}$ plays the role of the estimate of θ , whereas in Theorem 2 such a role is played by $\hat{\theta} + \beta(x)$. Note that in none of the two theorems, the parameter estimate is required to converge to the true value of the parameters, although in Theorem 2, the feedback law is required to converge, along trajectories, to the known parameter controller. This has a very important, possibly counterintuitive, consequence: the asymptotic nonadaptive controller $u = v(x, \hat{\theta}_\infty)$, where $\hat{\theta}_\infty = \lim_{t \rightarrow \infty} \hat{\theta}(t)$, provided the limit exists,

is not in general a stabilizing controller for system (6).

Example Consider the nonlinear system described by the equation $\dot{x} = u + \theta x^2$, with $x(t) \in \mathbb{R}$, $u(t) \in \mathbb{R}$, and $\theta \in \mathbb{R}$. A known parameter controller satisfying the assumptions of Theorem 1 (with $V(x) = x^2/2$) and of Theorem 2 (with $\beta(x) = x$) is $u = -x - \theta x^2$. The resulting update laws and feedback laws are (the subscripts “1” and “2” are used to refer to the construction in Theorems 1 and 2, respectively)

$$\dot{\hat{\theta}}_1 = x^3, \quad u_1 = -x - \hat{\theta} x^2,$$

and

$$\dot{\hat{\theta}}_2 = x, \quad u_2 = -x - (\hat{\theta} + x)x^2,$$

respectively. $\diamond$

The basic building blocks in Theorems 1 and 2 can be exploited repeatedly to design adaptive controllers for systems with a specific structure, for example, for systems described by the equations:

$$\begin{aligned}\dot{x}_1 &= x_2 + \varphi_1(x_1)^\top \theta, \\ \dot{x}_2 &= x_3 + \varphi_2(x_1, x_2)^\top \theta, \\ &\vdots \\ \dot{x}_i &= x_{i+1} + \varphi_i(x_1, \dots, x_i)^\top \theta, \\ &\vdots \\ \dot{x}_n &= u + \varphi_n(x_1, \dots, x_n)^\top \theta,\end{aligned}\quad (8)$$

with $x_i(t) \in \mathbb{R}$, for $i = 1, \dots, n$, $u(t) \in \mathbb{R}$, $\varphi_i : \mathbb{R}^i \rightarrow \mathbb{R}^q$, for $i = 1, \dots, n$, smooth mappings, and $\theta \in \mathbb{R}^q$. Note that the last of the Eqs. (8) can be replaced by

$$\dot{x}_n = \bar{\theta} u + \varphi_n(x_1, \dots, x_n)^\top \theta,$$

with $\bar{\theta} \in \mathbb{R}$, provided its sign is known (this latter requirement may be removed using the so-called Nussbaum gain). The parameter $\bar{\theta}$ is often referred to as the high-frequency gain of the system: a terminology borrowed from linear systems theory.

Output Feedback Adaptive Control

A key feature of the parameterized systems described so far is that these are linearly parameterized in θ . The linear parameterization allows developing systematic design tools, such as those given in Theorems 1 and 2. Such results, however, require full information on the state of the system. If only partial information on the state is available, one has to combine an estimator of the state with an update law. Such a combination requires either strong assumptions on the system or very specific structures. For example, it is feasible if the system is not only linearly parameterized in the parameter θ but it is also linearly parameterized in the unmeasured states, hence it is described by equations of the form:

$$\begin{aligned}\dot{x}_1 &= x_2 + \psi_1(x_1) + \varphi_1(x_1)^\top \theta, \\ \dot{x}_2 &= x_3 + \psi_2(x_1) + \varphi_2(x_1)^\top \theta, \\ &\vdots \\ \dot{x}_i &= x_{i+1} + \psi_i(x_1) + \varphi_i(x_1)^\top \theta + b_i u, \\ &\vdots \\ \dot{x}_{n-1} &= x_n + \psi_{n-1}(x_1) + \varphi_{n-1}(x_1)^\top \theta + b_{n-1} u, \\ \dot{x}_n &= \psi_n(x_1) + \varphi_n(x_1)^\top \theta + b_n u, \\ y &= x_1,\end{aligned}$$

with $x_i(t) \in \mathbb{R}$, for $i = 1, \dots, n$, $u(t) \in \mathbb{R}$, $y(t) \in \mathbb{R}$, $\varphi_i : \mathbb{R} \rightarrow \mathbb{R}^q$ and $\psi_i : \mathbb{R} \rightarrow \mathbb{R}$, for $i = 1, \dots, n$, smooth mappings, $\theta \in \mathbb{R}^q$ and $b = [b_1, \dots, b_{n-1}, b_n]^\top$ unknown, but such that the sign of b_n is known and the polynomial $b_n s^{n-i} + b_{n-1} s^{n-i-1} + \dots + b_i$ has all roots with negative real part: this implies that the system with input u and output y is minimum phase.

Nonlinear Parameterized Systems

Adaptive control of nonlinearly parameterized systems is an open area of research. The design of adaptive controllers relies often upon structural assumptions, for example the existence of a monotonic parameterization, as in the system described by the equation

$$\dot{x} = F(x, u) + \Phi(x, \theta),$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $\theta \in \mathbb{R}^q$, and $F : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$ and $\Phi : \mathbb{R}^n \times \mathbb{R}^q \rightarrow \mathbb{R}^n$ smooth mappings, and such that, for all x , the mapping Φ satisfies the monotonicity condition

$$(\theta_a - \theta_b)^\top (\Phi(x, \theta_a) - \Phi(x, \theta_b)) > 0,$$

for all $\theta_a \neq \theta_b$. Alternatively, the design may exploit the so-called over-parameterization, for example, the equation of the system

$$\dot{x} = u + \psi_1(x) \sin \theta + \psi_2(x) \cos \theta,$$

with $x(t) \in \mathbb{R}$, $u(t) \in \mathbb{R}$, and $\theta \in \mathbb{R}$, may be rewritten in over-parameterized form as

$$\dot{x} = u + \psi_1(x)\theta_1 + \psi_2(x)\theta_2,$$

with $\theta_i \in \mathbb{R}$, for $i = 1, 2$. Note that the over-parameterized form *overlooks* the important information that $\theta_1^2 + \theta_2^2 = 1$.

Summary and Future Directions

The problem of adaptive stabilization for nonlinear systems has been discussed. Two conceptual building blocks for the design of stabilizing adaptive controllers have been discussed and classes of systems for which these blocks allow to explicitly design adaptive controllers have been given. The role of parameter convergence, or lack thereof, has been briefly discussed together with connections between adaptive control and observer designs. The difficulties associated with non-full state measurement and with nonlinear parameterization have been also briefly highlighted. Several problems have not been discussed, for example model reference adaptive control, robust adaptive control, *universal* adaptive controllers, the use of projections to incorporate prior knowledge on the parameter, and adaptive control problems for systems with time-varying parameters. Details on these can be found in the recommended reading list.

Nonlinear Filters

Frederick E. Daum
Raytheon Company, Woburn, MA, USA

Abstract

Nonlinear filters estimate the state of dynamical systems given noisy measurements related to the state vector. In theory, such filters can provide optimal estimation accuracy for nonlinear measurements with nonlinear dynamics and non-Gaussian noise. However, in practice, the actual performance of nonlinear filters is limited by the curse of dimensionality. There are many different types of nonlinear filters, including the extended Kalman filter, the unscented Kalman filter, and particle filters.

Keywords

Bayesian · Computational complexity · Curse of dimensionality · Estimation · Extended kalman filter · Non-Gaussian · Particle filter · Prediction · Smoothing · Stability · Unscented kalman filter

Description of Nonlinear Filters

Nonlinear filters are algorithms that estimate the state vector (x) of a nonlinear dynamical system given measurements of nonlinear functions of the state vector corrupted by noise. Such filters also quantify the uncertainty in the resulting estimate of the state vector (e.g., using the error covariance matrix). Some nonlinear filters compute the entire probability density of the state vector conditioned on the set of measurements available, rather than computing a point estimate of the state vector (e.g., conditional mean or maximum likelihood). For some applications the conditional probability density of x is highly non-Gaussian (e.g., strongly multimodal). Even if the measurement noise and the process noise and the initial uncertainty in

x are all Gaussian, the conditional density of x can be non-Gaussian, owing to the nonlinearities in the dynamics or measurements. The dynamical systems can evolve in continuous time or discrete time, and the measurements can be made in continuous time or at discrete times. The most popular nonlinear filter in practical applications is the extended Kalman filter (EKF), but there are many other families of nonlinear filters, including particle filters, unscented Kalman filters (UKFs), batch least squares, exact finite-dimensional filters, Gaussian sum filters, cubature Kalman filters, etc. Table 1 summarizes the most popular nonlinear filters. The theory for nonlinear filters is relatively simple (see Ho and Lee 1964), but the crucial practical issue is computational complexity, even today with fast modern inexpensive computers, e.g., graphical processing units (GPUs). See Ristic et al. (2004) for a book which is both accessible to engineers and thorough.

Bayesian Formulation of Filtering Problem

The Bayesian approach to nonlinear filters is by far the most popular formulation of the problem (see Ho and Lee 1964), and it has virtually eliminated all other competing theories, because it is simple, general, systematic, and useful. All ten nonlinear filters listed in Table 1 are Bayesian. The Bayesian approach uses a model of the dynamics of x as well as a model of the measurements. For example, discrete-time dynamics and measurement models are typically of the form

$$\begin{aligned}x(t_{k+1}) &= f(x(t_k), t_k) + w(t_k) \\z(t_k) &= h(x(t_k), t_k) + v(t_k)\end{aligned}$$

in which $x(t_k)$ is the d -dimensional state vector at time t_k , $z(t_k)$ is the m -dimensional measurement vector at time t_k , v is the measurement noise, and w is the so-called process noise. Both v and w are often modeled as Gaussian zero-mean random processes with statistically independent values at

distinct discrete times, but these models could be highly non-Gaussian with statistically correlated random values. The initial probability density of x before any measurements are available is also used in the Bayesian formulations. Real physical systems are most commonly modeled as evolving in continuous time using Itô stochastic differential equations:

$$dx = f(x(t), t)dt + dw$$

However, most engineers would rather think of the above Itô equation as an ordinary differential equation driven by Gaussian white noise:

$$dx/dt = f(x(t), t) + dw/dt$$

Mathematicians prefer the Itô equation to avoid the embarrassment that the time derivative of $w(t)$ does not exist. For details of stochastic calculus, see Jazwinski (1998). Such mathematical subtleties rarely cause any trouble in practical engineering applications. We emphasize, however, that it is important to correctly model continuous-time random processes for the evolution of the state vector (x) in many practical applications. Similarly, one can model measurements in continuous time using Itô calculus:

$$dz = h(x(t), t)dt + dv$$

Most engineers consider continuous-time measurement models as impractical and unnecessarily complicated mathematically, because digital computers always require discrete-time measurements and there are no practical analog computers that can be used for nonlinear filtering, owing to the overwhelming superiority of digital computers in terms of accuracy, stability, dynamic range, and flexibility. Nevertheless, there are many papers published by researchers using continuous-time measurement models. But the vast majority of practical papers on nonlinear filters use discrete time measurement models for obvious reasons. This contrasts sharply with the practical importance of correctly modeling continuous-time random processes for the evolution of the state vector (x).

Nonlinear Filters, Table 1 Summary of nonlinear filters

Nonlinear filter	Conditional probability density	Computational complexity	Comments	References
1. Extended Kalman filter (EKF)	Gaussian	d^3	Gives good accuracy for many practical applications but can be highly suboptimal in difficult problems	Gelb et al. (1974)
2. Unscented Kalman filter(UKF)	Gaussian	d^3	Often the UKF beats the EKF, but sometimes the EKF is better than the UKF; see Noushin (2008) for details	Julier and Uhlmann (2003)
3. Batch least squares	Gaussian	d^3	Often beats the EKF accuracy but can fail for multimodal or other strongly non-Gaussian densities	Sorenson (1980)
4. Particle filter	Arbitrary	Varies from d^3 to exponential in d , depending on many features of the problem	Often beats the EKF accuracy but can fail due to the curse of dimensionality and particle degeneracy and ill-conditioning	Doucet (2011)
5. Cubature Kalman filter	Gaussian	d^3	Sometimes beats the EKF and UKF for difficult nonlinear non-Gaussian problems, but not always	Haykin (2010)
6. Gaussian sum	Arbitrary	Varies from d^3 to exponential in d , depending on many features of the problem	Beats the EKF for certain difficult nonlinear non-Gaussian problems	Sorenson (1988)
7. Exact finite-dimensional filters	Exponential family	d^3	Beats the EKF for certain difficult nonlinear non-Gaussian problems	Daum (2005)
8. Implicit particle filters	Arbitrary	Suffers from the curse of dimensionality (i.e., computation time grows exponentially in d)	Only low-dimensional numerical examples have been published so far	Chorin (2009)
9. Particle flow filter	Arbitrary	Faster than standard particle filters by many orders of magnitude for high-dimensional problems (but unfortunately there is no explicit formula for computation time)	Beats the EKF by orders of magnitude for certain difficult nonlinear non-Gaussian problems	Daum (2013)
10. Numerical solution of Fokker-Planck equation	Arbitrary	Suffers from the curse of dimensionality (i.e., computation time grows exponentially in d)	Beats the EKF by orders of magnitude for certain difficult nonlinear non-Gaussian problems	Ristic (2004)

Nonlinear Filter Algorithms

There is no universally best nonlinear filter for all applications, and there is much debate about which is the best nonlinear filter for any given application. Even if we knew the best nonlinear filter for a given computer, the answer could be very different for a different computer; in particular, some filters can exploit massively parallel processing architectures, whereas others cannot. Research and development of nonlinear filters should continue rapidly for the foreseeable future. More generally, there is no universal theory of computational complexity for practical algorithms of this type; perhaps the closest approximation to such a theory is “information-based complexity” (IBC); e.g., see Traub and Werschulz (1998) and Dick et al. (2013). The estimation accuracy of x and the computational complexity of the nonlinear filter are intimately connected, as shown below for particle filters. There is no useful way to quantify the computational complexity of nonlinear filters without also quantifying estimation accuracy of x . This contrasts with standard computational complexity theory (e.g., P vs. NP) because we are interested in approximations rather than exact solutions. This is the basic idea of IBC. In practice, engineers compare the estimation accuracy and computational complexity of different nonlinear filters using Monte Carlo simulations for specific applications and specific computers.

The most active area of current research in nonlinear filters is focused on particle filters, which have the promise of optimal accuracy for essentially any nonlinear filter problem, at the cost of very high computational complexity for high-dimensional problems. In the early days (1994–2004), researchers often asserted that particle filters “beat the curse of dimensionality,” but it is well known today that this assertion is wrong (e.g., see Daum 2005). Unfortunately, there is no useful theory of computational complexity for particle filters, but rather the currently available theory gives asymptotic bounds on accuracy with generic “constants.” Such bounds on the variance of estimation error are generally

of the form c/N in which N is the number of particles and c is the generic so-called constant. But we know that the so-called constant actually varies by many orders of magnitude depending on the specifics of the problem, including the following: (1) dimension of the state vector being estimated, (2) uncertainty in the initial state vector, (3) measurement accuracy, (4) stability of the dynamical system that describes the time evolution of the state vector, (5) geometry of the conditional probability densities (e.g., unimodal, log-concave, multimodal, etc.), (6) Lipschitz constants of the log probability densities, (7) curvature of the nonlinear dynamics and measurements, (8) ill-conditioning of the Fisher information matrix for the estimation problem, etc. Moreover, there are no tight bounds on the so-called constant c for practical nonlinear filter problems, but rather the best bounds for simple MCMC problems are known to be 30 orders of magnitude too large; see Dick et al. (2013).

Discrete-Time Measurement Models

Research papers on nonlinear filters are often mathematically abstract, but advanced math is not required for practical engineering applications (e.g., see Ho and Lee 1964). In particular, one can avoid the advanced stochastic mathematics used for continuous-time measurements by using discrete-time measurements, which is the practical case of interest anyway, owing to the use of digital computers to implement such algorithms. The notion that continuous-time measurements results in simpler, better, or more elegant results for nonlinear filters is misleading; for example, we have the elegant innovation theory for continuous-time measurements (Kailath 1970), but this theory is not applicable for discrete-time measurements, likewise with the elegant formula for propagating the conditional mean for continuous-time measurements (the so-called Fujisaki-Kallianpur-Kunita formula). More generally, the simple discrete-time version of Bayes’ rule suffices for practical real-world engineering applications; there is rarely a need to employ the more complex continuous-time version.

The discrete time formula for Bayes' rule is simply

$$p(x(t_k), t_k | Z_k) = p(x(t_k), t_k | Z_{k-1}) p(z_k | x(t_k)) / p(z_k | Z_{k-1})$$

in which

$p(x(t_k), t_k | Z_k)$ = probability density of x at time t_k conditioned on Z_k ; this is also called the “posteriori probability density”

$x(t)$ = state vector of the dynamical system at time t

Z_k = set of all measurements up to and including time t_k

z_k = measurement vector at time t_k

$p(z_k | x(t_k))$ = probability density of z_k conditioned on $x(t_k)$; this is also called the “likelihood”

$p(A|B)$ = probability density of A conditioned on B

This is all one needs to know about Bayes' rule for practical engineering applications of nonlinear filtering; see Ho and Lee (1964). Bayes' rule is a simple formula that multiplies two probability densities and normalizes it by dividing by $p(z_k | Z_{k-1})$. In most applications, there is no need to normalize the density, and hence, Bayes' rule for the unnormalized conditional density is even simpler:

$$p(x(t_k), t_k | Z_k) = p(x(t_k), t_k | Z_{k-1}) p(z_k | x(t_k))$$

We see that Bayes' rule for the unnormalized conditional density is simply a multiplication of two densities (i.e., the likelihood and the prior).

Summary and Future Directions

In practical applications, the most popular nonlinear filter is the extended Kalman filter (EKF), followed by the unscented Kalman filter (UKF). These two filters give good accuracy and robust performance for many practical applications. The computational complexity of both the EKF and UKF grows as the cube of the dimension of the state vector, and hence, they are very practical to run in real

time on laptops or PCs for many real-world applications. But there are also many difficult nonlinear or non-Gaussian problems for which the EKF and UKF give suboptimal accuracy, and in some cases, they give surprisingly bad accuracy. The accuracy of optimal nonlinear filters is limited by the curse of dimensionality. We know how to write the equations for the optimal nonlinear filter, but the solution generally takes an exponentially increasing time to compute as the dimension of the state vector grows. There are many different kinds of nonlinear filters, and this is still an active field of research, as shown in Crisan and Rozovskii (2011). Future research is likely to exploit advances in computational complexity theory for approximation of functions in the style of information-based complexity (IBC) rather than P vs. NP theory. This is because we want good fast approximations rather than exact algorithms. A lucid introduction to IBC is Traub and Werschulz (1998), and recent work is surveyed in Dick et al. (2013). Another fruitful direction of research is to exploit the recent advances in transport theory, as explained in Daum (2013); the best introduction to transport theory is the book by Villani (2003), which is very accessible yet thorough. Research in exact finite-dimensional filters is difficult but could yield substantial improvements in accuracy and computational complexity; for example, see Benes (1981), Marcus (1984), and Daum (2005). Progress in nonlinear filter research could be inspired by many diverse fields, including fluid dynamics, quantum chemistry, quantum field theory, gauge theory, string theory, Lie superalgebras, Lie supergroups, and neuroscience. An important open research topic is the stability of nonlinear filters, which is obviously a fundamental limitation to good theoretical upper bounds on estimation error. We still do not have a practical theory of stability for nonlinear filters. Perhaps the closest approximation to such a theory is the lucid paper by van Handel (2010), which makes an interesting attempt at understanding the stability of nonlinear filters. In particular, van Handel's paper aims to generalize Kalman's theory of

stability for the Kalman filter by connecting stability with the essence of controllability and observability. A good survey of what is known about stability theory for nonlinear filters is given in various articles in Crisan and Rozovskiĭ (2011).

Nonlinear Sampled-Data Systems

Dragan Nesić¹ and Romain Postoyan^{2,3}

¹Department of Electrical and Electronic Engineering, The University of Melbourne, Melbourne, VIC, Australia

²Université de Lorraine, CRAN, France

³CNRS, CRAN, France

Abstract

Sampled-data systems are control systems in which the feedback law is digitally implemented via a computer. They are prevalent nowadays due to the numerous advantages they offer compared to analog control. Nonlinear sampled-data systems arise in this context

when either the plant model or the controller is nonlinear. While their linear counterpart is now a mature area, nonlinear sampled-data systems are much harder to deal with and, hence, much less understood. Their inherent complexity leads to a variety of methods for their modeling, analysis, and design. A summary of these methods is presented in this entry.

Keywords

Discrete time · Nonlinear · Sampled data · Sampler · Zero-order hold

Introduction

Definition: A control system in which a continuous-time plant is controlled by a digital computer is referred to as a *sampled-data control system* or simply a *sampled-data system* (Chen and Francis 1994); see Fig. 1. *Nonlinear sampled-data systems* arise when either the model of the plant or the controller is nonlinear; otherwise the system is referred to as a linear sampled-data system.

Motivation: Sampled-data control is preferable to continuous-time (analog) control for a range of reasons including reduced cost, reduced wiring, more robust hardware, easier and more flexible programming, and so on. Nowadays, a large majority of controllers are implemented on digital computers, and, hence, sampled-data systems are prevalent in practice. On the other hand, nonlinear plant models are necessary in numerous applications when a wide range of operating conditions need to be considered or

when truly nonlinear phenomena, such as friction or state/input constraints, are not negligible. Hence, there are many situations where nonlinear plant models are essential, such as vertical takeoff and landing of an aircraft, robots, automotive engines, and biochemical reactors, to name a few. It has to be noted that the nonlinearity may also come from the controller even when we consider linear plants as it is the case in adaptive control or model predictive control with constraints, for example.

Structure of sampled-data systems: Figure 1 presents a typical structure of a sampled-data system which consists of a continuous-time plant, an analog-to-digital (A/D) converter (i.e., a sampler), a digital-to-analog (D/A) converter (i.e., a hold device), and a discrete-time controller.

The A/D converter takes measurements $y(t_k)$ of a continuous-time output signal $y(t)$, such as temperature or pressure, at sampling time instants $t_k, k = 0, 1, \dots$ and sends them to the control algorithm. The measurements are obtained with finite precision (i.e., they are quantized); this effect is not considered in this entry. The sampling instants t_k are often equidistant, that is, $t_k = kT, k = 0, 1, \dots$, where the distance T between any two consecutive sampling instants is referred to as the *sampling period*. The sampling period is an important degree of freedom in the design of sampled-data systems and it needs to be carefully selected.

The control algorithm is discrete in nature. It takes the sequence of measurements $y(t_k)$ and processes them to produce a sequence of control values $u(t_k)$. The D/A converter converts the sequence of control values $u(t_k)$

Nonlinear Sampled-Data

Systems,

Fig. 1 Sampled-data (control) system

into a continuous-time signal $u(t)$ that drives the actuators which control the plant. Typically, a zero-order hold is used, i.e., $u(t) = u(t_k), \forall t \in [t_k, t_{k+1})$. However, it is possible to use other types of holds.

Note that the system in Fig. 1 can be generalized in many ways. An important generalization is *multi-rate sampling* where the output of the system is sampled at one sampling rate while the control inputs are updated at a different sampling rate. Another generalization are *networked control systems* which are discussed in the last section.

Modeling

The combination of continuous-time and discrete-time components renders the analysis and the design of sampled-data systems challenging. Still, linear systems allow for computationally efficient analysis and design techniques that benefit from the z and δ transforms, as well as convex optimization (Chen and Francis 1994). Nonlinear sampled-data systems, on the other hand, are much harder to deal with since the aforementioned methods do not apply in this case. This inherent difficulty has led to a variety of models for different analysis and design methods:

1. Continuous-time models
2. Discrete-time models
3. Sampled-data models

We discuss below each of these models, their features, and the analysis or design methods that exploit them.

Continuous-time models basically ignore the sampling process and assume that all signals are continuous time. They are the coarsest approximation of the sampled-data system and they are useful only for very small sampling periods. Nevertheless, they are invaluable and are used as the first step in the controller/observer design in the so-called *emulation* design approach.

Discrete-time models only capture the behavior of the sampled-data system at sampling

instants. Indeed, they ignore the inter-sample behavior of the system and this is their main drawback. There are two ways in which nonlinear discrete-time models arise: (i) from the identification of the plant model using the sampled measurements and (ii) from the discretization of a known continuous-time plant model. For instance, black box identification methods often lead to nonlinear discrete-time models in input-output form, such as NARMA (nonlinear auto-regressive moving average) models (Chen et al. 1989; Juditsky et al. 1995). Depending on the approximating functions used, the nonlinearities can be polynomial, neural network type, fuzzy type, and so on. On the other hand, the discretization of the continuous-time plant model requires an exact analytic solution of a set of nonlinear differential equations. When such an analytic solution exists, we can obtain the exact discrete-time models of the system; this is typically assumed for linear plants. Nonlinear sampled-data systems are different from their linear counterparts in that it is typically impossible to obtain the exact discrete-time model and only approximate discrete-time models are available for analysis and design (Nešić et al. 1999; Nešić and Teel 2004).

Sampled-data models capture the true behavior of the sampled-data system including its inter-sample behavior. There are several ways in which this can be achieved. One way is to model the piecewise constant signals that arise from zero-order hold devices as signals with a time-varying delay; this gives rise to time-delay nonlinear models (Teel et al. 1998). Another recently proposed approach is to model nonlinear sampled-data systems as hybrid dynamical systems (Goebel et al. 2012). An extensive analysis and design toolbox has been developed for hybrid dynamical systems and these results can be used for nonlinear sampled-data systems. Another class of models, based on the so-called lifting, has been applied for linear systems where the system is represented as a discrete-time system with infinite dimensional input and output spaces. While this approach has been very successful in the linear context (Chen and Francis 1994), it appears that it is not as useful for

nonlinear systems due to difficulties arising from harder analysis and prohibitive computational requirements.

The Main Issues and Analysis

Controllability/observability: Issues arising due to sampling in linear systems transfer to the nonlinear context although they are less understood in this case. For instance, it is well known that sampling may “destroy” the controllability and/or observability properties of the system (Chen and Francis 1994). In other words, if the continuous-time plant model is controllable/observable, then the corresponding exact discrete-time model of the plant may not verify these properties for some sampling periods. A simple test is available for linear systems to avoid this phenomenon, but we are not aware of similar results in the nonlinear context.

Finite escape times: A major difference between continuous-time linear and nonlinear systems is that the former have well defined solutions for constant control inputs and arbitrarily long sampling periods. This is not the case, in general, for nonlinear systems as they may exhibit finite escape times. In other words, for a constant input it may happen for some initial conditions of a nonlinear system that solutions blow up within a time that is shorter than the sampling period. As a consequence, for such an initial condition and input, the exact discrete-time system cannot be defined. This is a fundamental obstacle to achieving global stability results for nonlinear systems if the sampling period is fixed and independent of the size of the initial state. Nevertheless, it is possible to ensure semi-global stability properties for very general nonlinear systems which means that any compact domain of convergence can be achieved if the sampling period is sufficiently reduced (Nešić and Teel 2004).

Model structure is changed: An important issue for nonlinear sampled-data systems is that the sampling modifies the structure of the model. When the continuous-time plant model has a

certain structure, such as triangular or affine in the input, the corresponding exact discrete-time model will not inherit it; see Monaco and Normand-Cyrot (2007) and Yuz and Goodwin (2005). This significantly complicates the design of sampled-data systems via the discrete-time approach since many nonlinear design techniques, like backstepping or forwarding, are heavily reliant on the structure of the model.

Zero dynamics: Probably the most significant aspect of the changed structure are the so-called sampling zeros. In linear systems, it is well known that if a continuous-time linear system of relative degree $r \geq 2$ is sampled, then generically for fast sampling the discrete-time models of the plant will have relative degree $r = 1$. In other words, sampling introduces extra zeros in the model which are often unstable and thus render the system non-minimum phase. It is well known that the controller design is much harder for non-minimum phase systems, and, moreover, there are certain fundamental performance limitations in this case. Recently, results that extend the notion of sampling zeros to the nonlinear sampled-data systems have been reported; see the references in Monaco and Normand-Cyrot (2007).

Passivity: Some plant properties like passivity are much more restrictive in discrete time than in continuous time. Indeed, it is necessary for a continuous-time plant to have relative degree 1 or 0 to be passive, whereas only relative degree 0 discrete-time plants may possess this property. In other words, an exact discrete-time model of a passive continuous-time plant of relative degree 1 will not be passive; that is, sampling typically destroys passivity.

Controller Design

Linearization: The simplest way to design sampled-data nonlinear systems is to linearize the plant at a given operating point. In this case, the nonlinear plant dynamics are approximated by a linear model around a chosen equilibrium, and

then any of the linear sampled-data techniques can be applied to the linearized model. The obtained solution is then implemented on the true nonlinear plant. The drawback of this technique is that the solution would typically perform well only in the vicinity of the selected equilibrium point.

Nonlinear methods: An alternative is to perform designs that rely on a nonlinear plant model. These approaches can be divided into feedback linearization, emulation design method, (approximate and exact) discrete-time design method, and sampled-data design method.

Feedback linearization: Some classical problems, like feedback linearization, are harder for sampled-data systems than continuous-time ones. It was shown that a class of discrete-time nonlinear systems for which feedback linearization is possible is smaller than the corresponding class of continuous-time systems (Grizzle 1987). This has led to approximate feedback linearization techniques which consider achieving feedback linearization approximately with an error that can be reduced by reducing the length of the sampling period (Arapostathis et al. 1989).

Continuous-time design method (Emulation design): Emulation is a design technique consisting of two steps. In the first step, a continuous-time controller or observer is designed for the continuous-time plant while ignoring sampling to achieve appropriate stability, performance, and/or robustness guarantees. In the second step, the designed controller/observer is discretized for implementation and the sampling period is reduced sufficiently for the method to work. This method is approximate since the continuous-time plant model approximates well the sampled-data systems only for sufficiently small sampling periods. The discretization can be done using various implicit or explicit Runge-Kutta methods, such as the forward or backward Euler method (Monaco and Normand-Cyrot 2007; Yuz and Goodwin 2005). The emulation method is probably the best understood of all design methods. It was shown that a range of stability properties that can be cast in terms of dissipation inequalities are preserved in an appropriate sense under the emulation approach (Laila et al. 2002). Moreover,

nonconservative estimates of the upper bound for the required sampling period in emulation have been reported recently (Nešić et al. 2009).

Exact discrete-time design method: Exact discrete-time design method assumes that an exact discrete-time model of the plant is available to the designer; see Kötta (1995) and the references cited therein. This approach is reasonable when black box identification techniques are used for modeling. Moreover, in some rare cases it is possible to obtain the exact discrete-time model of the plant by integrating the continuous-time model with fixed inputs (assuming the zero-order hold is used). This is the case when the plant dynamics are linear while the control law is nonlinear (e.g., adaptive control) or the plant is linear with state/input constraints, which is a setup often used in the model predictive control. The literature on exact discrete-time design method is vast and many of the nonlinear continuous-time design techniques, like backstepping, forwarding, and passivity-based designs, are extended to discrete-time nonlinear systems; see Kötta (1995) and Grizzle (1987). A drawback of these methods is that they assume a special structure of the discrete-time nonlinear model, such as upper or lower triangular structure, which is typically much more restrictive in discrete-time than in continuous-time due to the loss of structure due to sampling that was discussed earlier.

Approximate discrete-time design method: Due to the nonlinearity, it is impossible in most cases to obtain an exact discrete-time plant model by integrating its continuous-time model equations; instead, a range of approximate discrete-time plant models, such as Runge-Kutta, can be used for controller/observer design. It was recently shown that this design method may lead to disastrous consequences where the controller stabilizes the approximate discrete-time plant model for all (arbitrarily small) sampling periods while the same controller destabilizes the exact discrete-time plant model for all sampling periods; see Nešić and Teel (2004) and Nešić et al. (1999). This is true even for linear systems and some commonly used

discretization techniques and controller designs. These considerations have led to the development of a framework for controller design based on approximate discrete-time models (Nešić et al. 1999; Nešić and Teel 2004). This framework provides checkable conditions on the continuous-time plant model, the approximate discrete-time model and the controller that guarantee that the controllers designed in this manner would stabilize the exact discrete-time model and, hence, the nonlinear sampled-data system for sufficiently small sampling periods. The design is based on families of approximate discrete-time models parameterized with the sampling period, and the design objectives are more demanding than in the continuous-time nonlinear systems. Ideas from numerical analysis are adapted to this context. This framework was used to design controllers and observers for classes of nonlinear sampled-data systems where typically Euler approximate discretization is employed to generate the approximate discrete-time model.

Sampled-data design method: Both emulation and discrete-time design methods have their drawbacks. Indeed, the former method ignores the sampling at the design stage, whereas the latter method ignores and may produce unacceptable inter-sampling behavior. Thus, methods that use a sampled-data model of the plant for design are much more attractive. There are two possible ways in which this can be achieved for nonlinear sampled-data systems.

The first approach consists of representing nonlinear sampled-data systems as systems with time-varying delays (Teel et al. 1998). However, controller design tools for such systems need to be further developed.

The second approach involves representing the nonlinear sampled-data system as a hybrid dynamical system. Recent advances on modeling and analysis of hybrid dynamical systems (Goebel et al. 2012) offer great opportunities in this context, but the full potential of this approach is still to be exploited. Nonlinear sampled-data systems are just a small subclass of hybrid dynamical systems, and developing specific analysis and design tools tailored to this class of systems seems promising.

It should be emphasized that there are many related techniques, such as discrete-time adaptive control and model predictive control, that deal with classes of nonlinear sampled-data systems but are not a part of the mainstream nonlinear sampled-data literature.

Summary and Future Directions

Summary: Sampled-data control systems are nowadays prevalent and there are many situations where nonlinear models need to be used to deal with wider ranges of operating conditions, more restrictive constraints, and enhanced performance specifications. Despite their increasing importance, the design of nonlinear sampled-data systems remains largely unexplored, and it is much less developed than its continuous-time counterpart. A variety of models, analysis, and design techniques make nonlinear sampled-data literature very diverse and a comprehensive textbook reference or a unifying approach is still missing. Many open questions remain for nonlinear sampled-data systems, such as results on multi-rate sampling, design techniques based on sampled-data models, and other generalizations which are discussed below.

Future Directions: In the 1990s, a new generation of digitally controlled systems has evolved from the more classical sampled-data systems which are generally referred to as networked control systems (NCS); see Heemels et al. (2010) and the references cited therein. These systems exploit digital wired or wireless communication networks within the control loops. Such a setup is introduced to reduce the cost, weight, and volume of the engineered systems, but its special structure imposes new challenges due to the communication constraints, data packet dropouts, quantization of data, varying sampling periods, time delays, etc. At the same time, these systems provide new flexibilities due to the distributed computation within the control system that can be used to improve the performance and mitigate some of the undesirable network effects on the overall system performance. Moreover,

embedded microprocessors allow for event-triggered and self-triggered sampling (Anta and Tabuada 2010) that are still largely unexplored especially for nonlinear systems. Design of NCS was identified as one of the biggest challenges to the control research community in the twenty-first century, and more than a decade of intense research on this topic still has not provided a comprehensive and unifying approach for their analysis and design. Novel results on modeling and Lyapunov stability theory for (nonlinear) hybrid dynamical systems appear to offer the right analysis design tools but they are still to be converted into efficient and easy-to-use design tools in the control engineers' toolbox.

Nonlinear System Identification Using Particle Filters

Thomas B. Schön

Department of Information Technology, Uppsala University, Uppsala, Sweden

Abstract

Particle filters are computational methods opening up for systematic inference in nonlinear/non-Gaussian state-space models. The particle filter constitute the most popular sequential Monte Carlo (SMC) method. This

is a relatively recent development, and the aim here is to provide a brief exposition of these SMC methods and how they are key enabling algorithms in solving nonlinear system identification problems. The particle filters are important for both frequentist (maximum likelihood) and Bayesian nonlinear system identification.

Keywords

Bayesian · Backward simulation · Maximum likelihood · Markov chain Monte Carlo (MCMC) · Particle filter · Particle MCMC · Particle smoother · Sequential monte carlo

Introduction

The state-space model (SSM) offers a general tool for modeling and analyzing dynamical phenomena. The SSM consists of two stochastic processes: the states $\{\mathbf{x}_t\}_{t \geq 1}$ and the measurements $\{y_t\}_{t \geq 1}$, which are related according to

$$\mathbf{x}_{t+1} \mid (\mathbf{x}_t = x_t) \sim f_\theta(x_{t+1} \mid x_t, u_t), \quad (1a)$$

$$y_t \mid (\mathbf{x}_t = x_t) \sim h_\theta(y_t \mid x_t, u_t), \quad (1b)$$

and the initial state $\mathbf{x}_1 \sim \mu_\theta(x_1)$. We use boldface for random variables, and $\sim$ means “distributed according to.” The notation $\mathbf{x}_{t+1} \mid (\mathbf{x}_t = x_t)$ stands for the conditional probability of $\mathbf{x}_{t+1}$ given $\mathbf{x}_t = x_t$. The state process $\{\mathbf{x}_t\}_{t \geq 1}$ is a Markov process, implying that we only need to condition on the most recent state $\mathbf{x}_t$, since that contains all information about the past. Furthermore, θ denotes the parameters $f_\theta(\cdot)$ and $h_\theta(\cdot)$ that are probability density functions, encoding the dynamic and the measurement models, respectively. In the interest of a compact notation, we will suppress the input u_t throughout the text.

The SSM introduced in (1) is general in that it allows for nonlinear and non-Gaussian relationships. Furthermore, it includes both black box and gray box models on state-space form. Nonlinear black box and gray box models are

covered by ► [“Nonlinear System Identification: An Overview of Common Approaches.”](#) The off-line nonlinear system identification problem can (slightly simplified) be expressed as recovering information about the parameters θ based on the information in the T measured inputs $u_{1:T} \triangleq \{u_1, \dots, u_T\}$ and outputs $y_{1:T}$. For a thorough exposition of the system identification problem, we refer to ► [“System Identification: An Overview.”](#) Nonlinear system identification has a long history, and a common assumption of the past has been that of linearity and Gaussianity. This assumption is very restrictive, and we have now witnessed well over half a century of research devoted to finding useful approximate algorithms allowing this assumption to be weakened. This development has significantly intensified during the past two decades of research on sequential Monte Carlo (SMC) methods (including particle filters and particle smoothers). However, the use of SMC for nonlinear system identification is more recent than that. The aim here is to introduce the key ideas enabling the use of SMC methods in solving nonlinear system identification problems, and as we will see, it is not a matter of straightforward application. The development of SMC-based identification follows two clear trends that are indeed more general: (1) the problems we are working with are analytically intractable, and hence, the mind-set has to shift from searching for closed-form solutions to the use of *computational methods*, and (2) the new algorithms have basic building blocks that are themselves algorithms. Both these trends call for new developments.

Before the SMC methods are introduced in section [“Sequential Monte Carlo,”](#) their need is clearly explained by formulating both the Bayesian and the maximum likelihood identification problems in sections [“Bayesian Problem Formulation”](#) and [“Maximum Likelihood Problem Formulation,”](#) respectively. Solutions to these problems are then provided in sections [“Bayesian Solutions”](#) and [“Maximum Likelihood Solutions,”](#) respectively. Finally, we give some intuition for online (recursive) solutions in section [“Online Solutions,”](#) and in section [“Summary and Future Directions,”](#) we

conclude with a summary and directions for future research.

Bayesian Problem Formulation

In formulating the Bayesian problem, the parameters θ are modeled as unknown stochastic variables, i.e., the model (1) needs to be augmented with a prior density for the parameters $\theta \sim p(\theta)$. The aim in Bayesian system identification is to compute the posterior density of θ given the measurements $p(\theta | y_{1:T})$. More generally, we typically compute the joint posterior of the parameters θ and the states $\mathbf{x}_{1:T}$,

$$p(\theta, \mathbf{x}_{1:T} | y_{1:T}) = p(\mathbf{x}_{1:T} | \theta, y_{1:T})p(\theta | y_{1:T}). \quad (2)$$

By explicitly including the state variables $\mathbf{x}_{1:T}$ in the problem formulation according to (2), they take on the role of auxiliary variables. The reason for including the state variables $\mathbf{x}_{1:T}$ as auxiliary variables is that the alternative of excluding them would require us to analytically marginalize the states $\mathbf{x}_{1:T}$. This is not possible for the model (1) under study. However, once we have an approximation of $p(\theta, \mathbf{x}_{1:T} | y_{1:T})$ available, the density $p(\theta | y_{1:T})$ is easily obtained by straightforward marginalization.

Maximum Likelihood Problem Formulation

In formulating the maximum likelihood (ML) problem, the parameters θ are modeled as unknown deterministic variables. The ML formulation offers a systematic way of computing point estimates of the unknown parameters θ in a model, by making use of the information available in the obtained measurements $y_{1:T}$. The ML estimate is obtained by finding the θ that maximizes the so-called log-likelihood function, which is defined as

$$\ell_T(\theta) \triangleq \log p_\theta(y_{1:T}) = \sum_{t=1}^T \log p_\theta(y_t | y_{1:t-1}). \quad (3)$$

Note that we use θ as a subindex to denote that the corresponding probability density function

is parameterized by θ , analogously to what was done in (1). The one step ahead predictor $p_\theta(y_t | y_{1:t-1})$ is computed by marginalizing $p(y_t, x_t | y_{1:t-1}) = h_\theta(y_t | x_t)p_\theta(x_t | y_{1:t-1})$ w.r.t. x_t , i.e., integrating out x_t from $p(y_t, x_t | y_{1:t-1})$. To summarize, the ML estimate $\hat{\theta}^{\text{ML}}$ is obtained by solving the following optimization problem:

$$\hat{\theta}^{\text{ML}} \triangleq \arg \max_{\theta} \sum_{t=1}^T \log \int h_\theta(y_t | x_t) p_\theta(x_t | y_{1:t-1}) dx_t. \quad (4)$$

This problem formulation clearly reveals the important fact that the nonlinear state inference problem (here computing $p_\theta(x_t | y_{1:t-1})$) is inherent in any maximum likelihood formulation for identification of SSMs. For linear Gaussian models, the Kalman filter offers closed-form solutions for the state inference problem, but for nonlinear models, there are no closed-form solutions available.

Sequential Monte Carlo

Solving the nonlinear system identification problem implicitly requires us to solve various nonlinear state inference problems. We will, for example, need to approximate the smoothing density $p(\mathbf{x}_{1:T} | y_{1:T})$ and the filtering density $p(x_t | y_{1:t})$. The SMC samplers offer approximate solutions to these and other nonlinear state inference problems, where the accuracy is only limited by the available computational resources. This section only deals with the state inference problem, allowing us to drop the θ in the notation for brevity.

Most SMC samplers hinge upon importance sampling, motivating section “[Importance Sampling](#).” In section “[Particle Filter](#),” we make use of importance sampling in computing an approximation of the filtering density $p(x_t | y_{1:t})$, and in section “[Particle Smoother](#),” a particle smoothing strategy is introduced to approximately compute $p(\mathbf{x}_{1:T} | y_{1:T})$.

Importance Sampling

Let $\mathbf{z}$ be a random variable distributed according to some complicated density $\pi(\mathbf{z})$, and let $\varphi(\cdot)$ be some function of interest. Importance sampling offers a systematic way of evaluating integrals of the form

$$\mathbb{E}[\varphi(\mathbf{z})] = \int \varphi(\mathbf{z})\pi(\mathbf{z})d\mathbf{z}, \quad (5)$$

without requiring samples directly generated from $\pi(\mathbf{z})$. The density $\pi(\mathbf{z})$ is referred to as the *target* density, i.e., the density we are trying to sample from. The importance sampler relies on a *proposal* density $q(\mathbf{z})$, from which it is simple to generate samples, let $\mathbf{z}^i \sim q(\mathbf{z})$, $i = 1, \dots, N$. Since each sample $\mathbf{z}^i$ is drawn from the proposal density rather than from the target density $\pi(\mathbf{z})$, we must somehow account for this discrepancy. The so-called importance weights $\tilde{\mathbf{w}}^i = \pi(\mathbf{z}^i)/q(\mathbf{z}^i)$ encode the difference. By normalizing the weights $\mathbf{w}^i = \tilde{\mathbf{w}}^i / \sum_{j=1}^N \tilde{\mathbf{w}}^j$, we obtain a set of weighted samples $\{\mathbf{z}^i, \mathbf{w}^i\}_{i=1}^N$ that can be used to approximately evaluate the integral (5) resulting in $\mathbb{E}[\varphi(\mathbf{z})] \approx \sum_{i=1}^N \mathbf{w}^i \varphi(\mathbf{z}^i)$. For a general introduction to importance sampling we refer to Robert and Casella (2004).

Particle Filter

The solution to the nonlinear filtering problem is provided by the following two recursive equations:

$$p(x_t | y_{1:t}) = \frac{h(y_t | x_t)p(x_t | y_{1:t-1})}{p(y_t | y_{1:t-1})}, \quad (6a)$$

$$p(x_t | y_{1:t-1}) = \int f(x_t | x_{t-1}) p(x_{t-1} | y_{1:t-1}) dx_{t-1}. \quad (6b)$$

In the general case (1), there are no analytical solutions available for the above equations. The particle filter maintains an empirical approximation of the solution, which at time $t-1$ amounts to

$$\hat{p}^N(x_{t-1} | y_{1:t-1}) = \sum_{i=1}^N \mathbf{w}_{t-1}^i \delta_{\mathbf{x}_{t-1}^i}(x_{t-1}), \quad (7)$$

where $\delta_{\mathbf{x}_{t-1}^i}(x_{t-1})$ denotes the Dirac delta mass located at $\mathbf{x}_{t-1}^i$. Furthermore, $\mathbf{w}_{t-1}^i$ and $\mathbf{x}_{t-1}^i$ are referred to as the weights and the particles, respectively. We will now derive the particle filter by designing an importance sampler allowing us to approximately solve (6). The derivation is performed in an inductive fashion, starting by assuming that $p(x_{t-1} | y_{1:t-1})$ is approximated by (7). Inserting (7) into (6b) results in $\hat{p}^N(x_t | y_{1:t-1}) = \sum_{i=1}^N \mathbf{w}_{t-1}^i f(x_t | \mathbf{x}_{t-1}^i)$, which is used in (6a) to compute an *approximation* of the filtering density $p(x_t | y_{1:t})$ up to proportionality. Hence, this allows us to target $p(x_t | y_{1:t})$ using an importance sampler, where the form of $\hat{p}^N(x_t | y_{1:t-1})$ suggests that new samples can be proposed according to

$$\mathbf{x}_t^i \sim q(x_t | y_{1:t}) = \sum_{i=1}^N \mathbf{w}_{t-1}^i f(x_t | \mathbf{x}_{t-1}^i). \quad (8)$$

It is worth noting that we can obtain a more general algorithm by replacing $f(x_t | \mathbf{x}_{t-1}^i)$ in the above mixture with a density $q(x_t | \mathbf{x}_{t-1}^i, y_t)$. However, in the interest of a simple but still highly useful algorithm, we keep (8). The proposal density (8) is a weighted mixture consisting of N components, which means that we can generate a sample $\tilde{\mathbf{x}}_t^i$ from it via a two-step procedure: first we select which component to sample from, and secondly we generate a sample from that component. More precisely, the first part amounts to selecting one of the N particles $\{\mathbf{x}_{t-1}^i\}_{i=1}^N$ according to

$$\mathbb{P}(\tilde{\mathbf{x}}_{t-1} = \mathbf{x}_{t-1}^i | \{\mathbf{x}_{t-1}^j, \mathbf{w}_{t-1}^j\}_{j=1}^N) = \mathbf{w}_{t-1}^i,$$

where the selected particle is denoted as $\tilde{\mathbf{x}}_{t-1}$. By repeating this N times, we obtain a set of equally weighted particles $\{\tilde{\mathbf{x}}_{t-1}^i\}_{i=1}^N$, constituting an empirical approximation of $p(x_{t-1} | y_{1:t-1})$, analogously to (7). We can then draw $\mathbf{x}_t^i \sim f(x_t | \tilde{\mathbf{x}}_{t-1}^i)$ to generate a realization from the proposal (8). This procedure that turns a weighted set

Algorithm 1 Bootstrap particle filter (for $i = 1, \dots, N$)

1. **Initialization** ($t = 1$):
 - (a) Sample $\mathbf{x}_1^i \sim \mu(x_1)$.
 - (b) Compute the importance weights $\tilde{\mathbf{w}}_1^i = h(y_1 | \mathbf{x}_1^i)$ and normalize $\mathbf{w}_1^i = \tilde{\mathbf{w}}_1^i / \sum_{j=1}^N \tilde{\mathbf{w}}_1^j$.
 2. **For** $t = 2$ **to** T **do**:
 - (a) Resample $\{\mathbf{x}_{t-1}^i, \mathbf{w}_{t-1}^i\}$ resulting in equally weighted particles $\{\tilde{\mathbf{x}}_{t-1}^i, 1/N\}$.
 - (b) Sample $\mathbf{x}_t^i \sim f(x_t | \tilde{\mathbf{x}}_{t-1}^i)$.
 - (c) Compute the importance weights $\tilde{\mathbf{w}}_t^i = h(y_t | \mathbf{x}_t^i)$ and normalize $\mathbf{w}_t^i = \tilde{\mathbf{w}}_t^i / \sum_{j=1}^N \tilde{\mathbf{w}}_t^j$.
-

of samples into an unweighted one is commonly referred to as *resampling*.

Finally, using the approximation $\hat{p}^N(x_t | y_{1:t-1})$ in (6a) and the proposal density according to (8) allows us to compute the weights as $\tilde{\mathbf{w}}_t^i = h(y_t | \mathbf{x}_t^i)$. Once all the N weights are computed and normalized, we obtain a collection of weighted particles $\{\mathbf{x}_t^i, \mathbf{w}_t^i\}_{i=1}^N$ targeting the filtering density at time t . We have now (in a slightly nonstandard fashion) derived the so-called *bootstrap particle filter*, which was the first particle filter introduced by Gordon et al. (1993) two decades ago. Since the introduction of Algorithm 1, the surrounding theory and practice have undergone significant developments; see, e.g., Doucet and Johansen (2011) for an up-to-date survey. The weights $\{\mathbf{w}_{1:T}^i\}_{i=1}^N$ and the particles $\{\mathbf{x}_{1:T}^i\}_{i=1}^N$ are random variables, and in executing the algorithm, we generate one realization from these. This is a useful insight both when it comes to understanding but also when it comes to the analysis of the particle filters. There is by now a fairly good understanding of the convergence properties of the particle filter; see, e.g., Doucet and Johansen (2011) for basic results and further pointers into the literature.

Particle Smoother

A particle smoother is an SMC method targeting the joint smoothing density $p(x_{1:T} | y_{1:T})$ (or one of its marginals). There are several different strategies for deriving particle smoothers. Rather than mentioning them all, we introduce one powerful and increasingly popular strategy based on

backward simulation, giving rise to the family of *forward filtering/backward simulation* (FFBSi) samplers.

In an FFBSi sampler, the joint smoothing density $p(x_{1:T} | y_{1:T})$ is targeted by complementing a forward particle filter with a second recursion evolving in the time-reversed direction. The following factorization of the joint smoothing density

$$p(x_{1:T} | y_{1:T}) = \left(\prod_{t=1}^{T-1} p(x_t | x_{t+1}, y_{1:t}) \right) p(x_T | y_{1:T}),$$

immediately suggests a highly useful time-reversed recursion. Start by generating a sample $\tilde{\mathbf{x}}_T \sim p(x_T | y_{1:T})$. We then continue generating samples backward in time by sampling from the so-called backward kernel $p(x_t | x_{t+1}, y_{1:t})$ according to $\tilde{\mathbf{x}}_t \sim p(x_t | \tilde{x}_{t+1}, y_{1:t})$, for $t = T-1, \dots, 1$. The resulting sample $\tilde{\mathbf{x}}_{1:T} \triangleq (\tilde{x}_1, \dots, \tilde{x}_T)$ is then by construction a sample from the joint smoothing density. Hence, in performing M backward simulations, we obtain the following approximation of the joint smoothing density:

$$\hat{p}^M(x_{1:T} | y_{1:T}) = \sum_{i=1}^M \frac{1}{M} \delta_{\tilde{\mathbf{x}}_{1:T}^i}(x_{1:T}). \quad (9)$$

For details on how to design algorithms implementing the backward simulation strategy, derivations, properties, and references, we refer to the survey on backward simulation methods by Lindsten and Schön (2013).

Bayesian Solutions

Strategies

The posterior density (2) is analytically intractable, but we can make use of Markov chain Monte Carlo (MCMC) samplers to address the inference problem. An MCMC sampler allows us to approximately generate samples from an arbitrary target density $\pi(z)$. This is done by

simulating a Markov chain (i.e., a Markov process) $\{\mathbf{z}[r]\}_{r \geq 1}$, which is constructed in such a way that the stationary distribution of the chain is given by $\pi(\mathbf{z})$. The sample paths $\{\mathbf{z}[r]\}_{r=1}^R$ of the chain can then be used to draw inference about the target distribution. Two *constructive* ways of finding a suitable Markov chain to simulate are provided by the Metropolis Hastings (MH) and the Gibbs samplers, where the latter can be interpreted as a special case of the former. See, e.g., Robert and Casella (2004) for details on MCMC. A Gibbs sampler targeting $p(\theta, x_{1:T} \mid y_{1:T})$ is given by

- (i) Draw $\theta' \sim p(\theta \mid x_{1:T}, y_{1:T})$.
- (ii) Draw $x'_{1:T} \sim p(x_{1:T} \mid \theta', y_{1:T})$.

The second step is hard, since it requires us to generate a sample from the joint smoothing density. Simply replacing step (ii) with a backward simulator does not result in a valid method (Andrieu et al. 2010).

One interesting solution is provided by the family of particle MCMC (PMCMC) sampler, first introduced by Andrieu et al. (2010). PMCMC provides a systematic way of combining SMC and MCMC, where SMC is used to construct the proposal density for the MCMC sampler. The so-called *particle Gibbs* (PG) sampler resolves the problems briefly mentioned above by a nontrivial modification of the SMC algorithm. Introducing the PG sampler lies outside the scope of this work; we refer the reader to the groundbreaking work by Andrieu et al. (2010).

A Nontrivial Example

To place PMCMC in the context of nonlinear system identification, we will now solve a nontrivial identification problem. The PG sampler is used to compute the posterior density for a general Wiener model (linear Gaussian system followed by a static nonlinearity) (Giri and Bai 2010):

$$\mathbf{x}_{t+1} = (\mathbf{A} \ \mathbf{B}) \begin{pmatrix} \mathbf{x}_t \\ \mathbf{u}_t \end{pmatrix} + \mathbf{v}_t, \quad \mathbf{v}_t \sim \mathcal{N}(\mathbf{0}, \mathbf{Q}), \quad (10a)$$

$$\mathbf{z}_t = \mathbf{C}\mathbf{x}_t, \quad (10b)$$

$$\mathbf{y}_t = \mathbf{g}(\mathbf{z}_t) + \mathbf{e}_t, \quad \mathbf{e}_t \sim \mathcal{N}(\mathbf{0}, \mathbf{r}). \quad (10c)$$

Based on observed inputs $u_{1:T}$ and outputs $y_{1:T}$, we wish to identify the model (10). We place a matrix normal inverse Wishart (MNIW) prior on $\{(\mathbf{A}, \mathbf{B}), \mathbf{Q}\}$, an inverse gamma prior on $\mathbf{r}$, and a Gaussian process (Rasmussen and Williams 2006) prior on the function $\mathbf{g}$, resulting in a semiparametric model. We can without loss of generality fix the matrix $\mathbf{C}$ according to $\mathbf{C} = (1, 0, \dots, 0)$. For a complete model specification, we refer to Lindsten et al. (2013).

The posterior distribution $p(\theta, x_{1:T} \mid y_{1:T})$ is computed using a newly developed PG sampler referred to as particle Gibbs with ancestor sampling (PGAS); see Lindsten et al. (2014). In the present experiment, we make use of $T = 1,000$ observations. The dimension of the state-space is 6, the linear dynamics contains complex poles resulting in oscillations as seen in Fig. 1, and the nonlinearity is non-monotonic; see Fig. 2. A subspace method is used to find an initial guess for the linear system, and the static nonlinearity is initialized using a linear function (i.e., a straight line).

It is worth pausing for a moment to reflect upon the posterior distribution $p(\theta, x_{1:T} \mid y_{1:T})$ that we are computing. The unknown “parameters” θ live in the space $\Theta = \mathbb{R}^{64} \times \mathcal{F}$, where $\mathcal{F}$ is an appropriate function space. The states $x_{1:T}$ live in the space $\mathbb{R}^{6 \times 1,000}$. Hence, $p(\theta, x_{1:T} \mid y_{1:T})$ is actually a rather complicated object for this example.

Using the PGAS sampler (with $N = 15$ particles), we construct a Markov chain $\{\theta[r], x_{1:T}[r]\}_{r=1}^R$ with $p(\theta, x_{1:T} \mid y_{1:T})$ as its stationary distribution. We run this Markov chain for $R = 25,000$ iterations, where the first 10,000 are discarded. The result is visualized in Figs. 1 and 2, where we plot the Bode diagram for the linear system and the static nonlinearity, respectively. In both figures we also provide the 99% Bayesian credibility interval. MATLAB code for Bayesian identification of Wiener models is available from user.it.uu.se/thosc112/research/software.html.

The resonance peaks are accurately modeled, but the result is less accurate at low frequencies (likely due to a lack of excitation). The fact that the posterior mean is inaccurate at low frequencies is encoded in our estimate of the posterior distribution as shown by the credibility intervals.

In Figs. 1 and 2, we have visualized not only the posterior mean but also the uncertainty for the entire model. We could do this since the model is a linear dynamical system followed by a static nonlinearity. It would be most interesting if we can come up with ways in which we could visualize the uncertainty inherent in general nonlinear dynamical systems.

Maximum Likelihood Solutions

Identifying the parameters θ in a general nonlinear SSM using maximum likelihood amounts to solving the optimization problem (3). This is a challenging problem for several reasons, for example, it requires the computation of the predictor density $p_\theta(y_t | y_{1:t-1})$. Furthermore, its

gradient (possibly also its Hessian) is very useful in setting up an efficient optimization algorithm. There are no closed-form solutions available for these objects, forcing us to rely on approximations. The SMC methods briefly introduced in section “[Sequential Monte Carlo](#)” provide rather natural tools for this task, since they are capable of producing approximations where the accuracy is only limited by the available computational resources.

To establish a clear interface between the maximum likelihood problem (3) and the SMC methods, it has proven natural to make use of the expectation maximization (EM) algorithm (Dempster et al. 1977). The EM algorithm proceeds in an iterative fashion to compute ML estimates of unknown parameters θ in probabilistic models involving latent variables. The strategy underlying the EM algorithm is to exploit the structure inherent in the probabilistic model to separate the original problem into two closely linked problems. The first problem amounts to computing the so-called *intermediate quantity*

Nonlinear System Identification Using Particle Filters, Fig. 1 Bode diagram of the sixth-order linear system. The *black curve* is the true system. The *red curve* is

the estimated posterior mean of the Bode diagram, and the *shaded area* is the 99% Bayesian credibility interval

Nonlinear System Identification Using Particle Filters, Fig. 2

The *black curve* is the true static nonlinearity (non-monotonic). The *red curve* is the estimated posterior mean of the static nonlinearity, and the *shaded area* is the 99% Bayesian credibility interval

$$\begin{aligned} \mathcal{Q}(\theta, \theta') &\triangleq \int \log p_{\theta}(x_{1:T}, y_{1:T}) \\ &\quad p_{\theta'}(x_{1:T} | y_{1:T}) dx_{1:T} \\ &= E_{\theta'} [\log p_{\theta}(x_{1:T}, y_{1:T}) | y_{1:T}], \end{aligned} \quad (11)$$

where we have already made use of the fact that the latent variables in an SSM are given by the states. Furthermore, θ' denotes a particular value for the parameters θ . We can show that by choosing a new θ such that $\mathcal{Q}(\theta, \theta') \geq \mathcal{Q}(\theta', \theta')$, the likelihood is either increased or left unchanged, i.e., $\ell_T(\theta) \geq \ell_T(\theta')$.

The EM algorithm now suggests itself in that we can generate a sequence of iterates $\{\theta^k\}_{k \geq 1}$ that guarantees that the log-likelihood is not decreased for increasing k by alternating the following two steps: (1) (expectation) compute the intermediate quantity $\mathcal{Q}(\theta, \theta^k)$, and (2) (maximization) compute the subsequent iterate θ^{k+1} by maximizing $\mathcal{Q}(\theta, \theta^k)$ w.r.t. θ . This procedure is then repeated until convergence, guaranteeing convergence to a stationary point on the likelihood surface.

The FFBSi particle smoother offers an approximation of the joint smoothing density $p_{\theta'}(x_{1:T} | y_{1:T})$ according to (9), which inserted into (11) provides an approximative solution $\hat{\mathcal{Q}}^M(\theta, \theta')$ to the expectation step. In solving the maximization step, we typically want gradients of the intermediate quantity $\nabla_{\theta} \hat{\mathcal{Q}}^M(\theta, \theta')$. These can also

be approximated using (9). The above development is summarized in Algorithm 2, providing a solution where the basic building blocks are themselves complex algorithms, an SMC algorithm for the E step and a nonlinear optimization algorithm for the M step. This means that we have the option of replacing the FFBSi particle smoother in step 2a with any other algorithm capable of producing estimates of the joint smoothing density. The family of PMCMC methods introduced in section “Bayesian Solutions” contains several highly interesting alternatives. A detailed account on Algorithm 2 is provided by Schön et al. (2011); see also Cappé et al. (2005).

Finally, we mention Fisher’s identity opening up yet another avenue for designing ML estimators using SMC approximations. Even if

Algorithm 2 EM for nonlinear system identification

1. **Initialization:** Set $k = 0$ and initialize θ^k .
2. **Expectation (E) step:**
 - (a) Compute an approximation $\hat{p}_{\theta^k}^M(x_{1:T} | y_{1:T})$, for example, using an FFBSi sampler.
 - (b) Calculate $\hat{\mathcal{Q}}^M(\theta, \theta^k)$.
3. **Maximization (M) step:** Compute

$$\theta_{k+1} = \arg \max_{\theta} \hat{\mathcal{Q}}^M(\theta, \theta^k).$$

4. Check termination condition. If satisfied, terminate; otherwise, update $k \rightarrow k + 1$ and return to step 2.
-

we are not interested in using EM when solving the nonlinear system identification problem, the intermediate quantity (11) is useful. The reason is provided via *Fisher's identity*,

$$\begin{aligned}\nabla_{\theta} \ell_T(\theta) \Big|_{\theta=\theta'} &= \nabla_{\theta} \mathcal{Q}(\theta, \theta') \Big|_{\theta=\theta'} \\ &= \int \nabla_{\theta} \log p_{\theta}(x_{1:T}, y_{1:T}) \Big|_{\theta=\theta'} \\ &\quad p_{\theta'}(x_{1:T} \mid y_{1:T}) dx_{1:T},\end{aligned}$$

which provides a means to compute approximations of the log-likelihood gradient. Hessian approximations are also available, but these are more involved. Hence, Fisher's identity opens up for direct use of any off-the-shelf gradient-based optimization method in solving (4).

Online Solutions

Online (also referred to as recursive or adaptive) identification refers to the problem where the parameter estimate is updated based on the parameter estimate at the previous time step and the new measurement. This is used when we are dealing with big data sets and in real-time situations. SMC offers interesting opportunities when it comes to deriving online solutions for nonlinear state-space models. The most direct idea is simply to make use of a gradient method

$$\theta_t = \theta_{t-1} + \gamma_t \nabla_{\theta} \log p_{\theta}(y_t \mid y_{1:t-1}),$$

where $\{\gamma_t\}$ is the sequence of step sizes. Fisher's identity (12) opens up for the use of SMC in approximating $\nabla_{\theta} \log p_{\theta}(y_t \mid y_{1:t-1})$. However, this leads to a rapidly increasing variance, something that can be dealt with by the so-called "marginal" Fisher identity; see Poyiadjis et al. (2011) for details.

An interesting alternative is provided by an online EM algorithm; see, e.g., Cappé (2011) for a solid introduction. The online EM approaches rely on the additive properties of the $\mathcal{Q}$ -function. The area of online solutions via SMC is likely to grow in the future as there is a clear need

motivated by the constantly growing data sets and there are also clear theoretical opportunities.

Summary and Future Directions

We have discussed how SMC-based algorithms can be used to solve nonlinear system identification problems, by sketching both Bayesian and ML solutions. A common feature of the resulting algorithms is that they are (nontrivial) combinations of more basic algorithms. We have, for example, seen the combined use of a particle smoother and a nonlinear optimization solver in Algorithm 2 to compute ML estimates. As another example we have the class of PMCMC methods, where the basic building blocks are provided by SMC samplers and MCMC samplers. The use of SMC and MCMC methods for nonlinear system identification has only just started to take off, and it presents very interesting future prospects. Some directions for future research are as follows: (1) The family of PMCMC algorithms is rich and fast growing, with great potential for further developments. For example, its use in solving the state smoothing problem (i.e., computing $p(x_{1:T} \mid y_{1:T})$) is likely to provide better algorithms in the near future. (2) Related to this is the potential to design new particle smoothers capable of generating new particles also in the time-reversed direction. (3) There are open and highly relevant challenges when it comes to designing backward simulators for Bayesian nonparametric methods (Hjort et al. 2010). A key question here is how to represent the backward kernel $p(x_t \mid x_{t+1}, y_{1:t})$ in such nonparametric settings. (4) The use of Bayesian nonparametric models will open up interesting possibilities for hybrid system identification, since they allow us to systematically express and work with uncertainties over segmentations.

Nonlinear System Identification: An Overview of Common Approaches

Qinghua Zhang
Inria, Campus de Beaulieu,
Rennes Cedex, France

Abstract

Nonlinear mathematical models are essential tools in various engineering and scientific domains, where more and more data are recorded by electronic devices. How to build nonlinear mathematical models essentially based on experimental data is the topic of this entry. Due to the large extent of the topic, this entry provides only a rough overview of some well-known results, from gray-box to black-box system identification.

Keywords

Black-box models · Block-oriented models · Gray-box models · Nonlinear system identification

Introduction

The wide success of linear system identification in various applications (Ljung 1999; ► [System Identification: An Overview](#)) does not necessarily mean that the underlying dynamic systems are intrinsically linear. Quite often, linear system identification can be successfully applied to a nonlinear system if its working range is restricted to a neighborhood of some working point. Nevertheless, some advanced engineering systems may exhibit significant nonlinear behaviors under their normal working conditions, so do most biological or social systems. There is therefore an increasing demand on nonlinear dynamic system modeling theory. Nonlinear system identification is studied to partly answer this demand, when experimental data carry the essential information for modeling purpose.

Nonlinear system identification, compared to its linear counterpart, is a much more vast topic, as in principle a nonlinear model can be *any* description of a system which is not linear. For this reason, this entry provides only a rough overview of some well-known results.

An overview of the basic concepts of system identification can be found in ► [System Identification: An Overview](#), notably the five basic elements to be taken into account in each application, among which the (nonlinear) model structures will be mainly focused on by this entry, as they represent the essential particularities of nonlinear system identification problems.

The various model structures used in nonlinear system identification are often classified by the level of available prior knowledge about the considered system: from *white-box* models to *black-box* models, via *gray-box* models. In principle, a white-box model is fully built from prior knowledge. Such a fully white-box approach is rarely feasible for complex systems because of insufficient prior knowledge or of intractable system complexity. Therefore, the system identification methods summarized in this entry concern gray-box and black-box models, for which experimental data play an essential role.

For ease of presentation, the main content of this entry will be restricted to the single-input

single-output (SISO) case. The multiple-input multiple-output (MIMO) case will be discussed in the section “[Multiple-Input Multiple-Output Systems](#).”

Gray-Box Models

This section covers gray-box models, from the most to the least demanding ones in terms of prior knowledge.

Parametrized Physical Models

The dynamic behaviors of some engineering systems are governed by well-known physical laws, typically in the form of differential equations, often with unknown parameters. These parametrized physical equations can be used as gray-box models for system identification. In most situations, such a model can be written in the form of a vectorial first-order ordinary differential equation (ODE), known as *state equation*, and can be generally written as

$$\frac{dx(t)}{dt} = f(x(t), u(t); \theta) \quad (1)$$

where t represents the time, $x(t)$ is the *state* vector, $u(t)$ is the *input*, and $f(\cdot)$ is a (nonlinear) function parametrized by the vector θ .

The observation on the system (typically with electronic sensors), referred to as the *output* and denoted by $y(t)$, is related to $x(t)$ and $u(t)$ through another known parametrized equation

$$y(t) = h(x(t), u(t); \theta) + v(t) \quad (2)$$

where $v(t)$ represents the measurement error.

With digital electronic instruments, the input $u(t)$ and the output $y(t)$ are sampled at some discrete-time instants, say $t = \tau, 2\tau, 3\tau, \dots, N\tau$ with some constant sampling period $\tau > 0$. For the sake of notation simplicity, let the sampling period $\tau = 1$ and assume ideal instantaneous samplers; then the sampled input-output data set is denoted by

$$Z^N = \{u(1), y(1), u(2), y(2), \dots, u(N), y(N)\}. \quad (3)$$

In some applications, data samples are made at irregular time instants. Some studies are particularly focused on system identification in this case (Garnier and Wang 2008).

The main remaining task of gray-box system identification is to estimate the parameter vector θ from the data set Z^N . The identification criterion is typically defined with the aid of an output predictor derived from the system model. A natural output predictor is simply based on the numerical solution of the state equation (1): for some given value of θ , initial state $x(0)$ and some assumed inter-sample behavior of the input $u(t)$ (e.g., with a zero order hold), the trajectory of $x(t)$, denoted by $\hat{x}(t|\theta)$, is computed with a numerical ODE solver, then the output prediction is computed as

$$\hat{y}(t|\theta) = h(\hat{x}(t|\theta), u(t); \theta). \quad (4)$$

The parameter vector θ is typically estimated by minimizing the sum of squared prediction error $\varepsilon(t|\theta) = y(t) - \hat{y}(t|\theta)$. See ► [System Identification: An Overview](#) and (Bohlin 2006) for more details.

The predictor based on the numerical solution of the state equation (1) (known as a *simulator*) may be in trouble if this equation with the given value of θ is unstable. Moreover, the state equation (1) may also be subject to some modeling error that should be taken into account in the output predictor. In such cases, the output predictor can be made with the aid of some nonlinear state observer (Gauthier and Kupka 2001) or some nonlinear filtering algorithm (Doucet and Johansen 2011).

Alternatively, sequential Monte Carlo (SMC) methods can also be applied to the identification of (small size) nonlinear state-space systems, typically assuming a discrete-time counterpart of the model described by Eqs. (1) and (2). See ► [Nonlinear System Identification Using Particle Filters](#).

The gray-box approach is particularly useful in engineering fields where some software libraries of commonly used components are

available. In this case, a system model can be built by connecting available component models. Nevertheless, the “connection” of the component models may introduce algebraic constraints through variables shared by connected components, leading to *differential algebraic equations* (DAE), which are a wider class of dynamic system models than the abovementioned state-space models (► [Modeling of Dynamic Systems from First Principles](#)). For most dynamic systems, it is possible to avoid the DAE formulation by causality analysis, so that the connections between different system components are treated as information flow, instead of algebraic constraints. There exist also some theoretic studies on DAE system identifiability (Ljung and Glad 1994) and some recent developments on the identification of such systems (Gerding et al. 2007).

Combined Physical and Black-Box Models

It may happen that, in a complex system, part of the components is well described by physical laws (possibly with available models from a software library), but some other components are not well studied. In this case, the latter components can be dealt with black-box models (or possibly empirical models). The entire model can be fitted to a collected data set Z^N , like in the case of the previous subsection.

Block-Oriented Models

Complex systems, notably those studied in engineering, are often made of a certain number of components; thus a system model can be built by connecting component models. In this sense, such component-based models could be said “block-oriented.” In the system identification literature, the term *block-oriented model* is often used in a particular context (Giri and Bai 2010), where it is typically assumed that each component is either a *linear dynamic* subsystem or a *nonlinear static* one. Here, the term “static” means that the behavior of the component is memoryless and can be described by an algebraic equation. The study of system identification with such models is motivated by the fact that, when a controlled system is stabilized around a working

point, its dynamic behavior can be well described by a linear model, but its actuators and sensors may exhibit significant nonlinear behaviors like saturation or dead zone. The choice of a particular block-oriented model structure depends on the prior knowledge about the underlying system, with specific identification methods available for different model structures.

The most frequently studied block-oriented models for system identification concern the Hammerstein system and the Wiener system, each composed of two blocks, as illustrated, respectively, in Figs. 1 and 2.

Hammerstein System Identification

A SISO Hammerstein system is typically formulated as

$$x(t) = f(u(t)) \quad (5a)$$

$$\begin{aligned} y(t) + a_1 y(t-1) + \cdots + a_{n_a} y(t-n_a) \\ = b_1 x(t-1) + \cdots + b_{n_b} x(t-n_b) \\ + v(t). \end{aligned} \quad (5b)$$

If the nonlinearity $f(\cdot)$ is expressed in the form of

$$f(u) = \sum_{l=1}^m \gamma_l \kappa_l(u) \quad (6)$$

with some chosen basis functions $\kappa_l(\cdot)$, then the identification problem amounts to fitting

Nonlinear System Identification: An Overview of Common Approaches, Fig. 1 Hammerstein system

Nonlinear System Identification: An Overview of Common Approaches, Fig. 2 Wiener system

the model parameters γ_l, a_i, b_j to a collected data set Z^N . A well-known method is based on over-parametrization (Bai 1998): replace in (5b) each $x(t-j)$ with the right-hand side of (6) and treat each parameter product $b_j \gamma_l$ as an individual parameter; then the newly parametrized model is equivalent to a linear ARX model (► [System Identification: An Overview](#)), which can be estimated by a well-established linear system identification method. As the $n_b + m$ parameters b_j and γ_l are replaced by $n_b m$ parameters in the new parametrization, the term “over-parametrization” refers to the fact that typically $n_b + m < n_b m$. The estimated over-parametrized model can be reduced to the original parametrization, usually through the singular value decomposition (SVD) of the matrix filled with the estimated parameter products $b_j \gamma_l$. See Giri and Bai (2010) for other identification methods with variant formulations of Hammerstein system model.

When the linear subsystem is approximated by a finite impulse response (FIR) model, it is possible to first estimate the linear model before estimating a model for the nonlinear block (Greblicki and Pawlak 1989).

Wiener System Identification

A SISO Wiener system is typically formulated as

$$z(t) = \sum_{k=1}^{\infty} h_k u(t-k) \quad (7a)$$

$$y(t) = g(z(t)) + v(t) \quad (7b)$$

where the sequence $h_1, h_2, \dots$ is the impulse response of the linear subsystem, $g(\cdot)$ is some nonlinear function, and $v(t)$ is a noise independent of the input $u(t)$.

Some methods for Wiener system identification assume a finite impulse response (FIR) of the linear subsystem. In this case, the linear subsystem model is characterized by the vector collecting the FIR coefficients $h^T = [h_1, h_2, \dots, h_n]$. There are two typical kinds of efficient solutions, assuming either the Gaussian distribution of the input $u(t)$ (Greblicki 1992) or the monotonicity

of the nonlinear function $g(\cdot)$ (Bai and Reyland 2008). In both cases, it is possible to directly estimate the FIR coefficients h from the input-output data Z^N , without explicitly estimating the unknown nonlinear function $g(\cdot)$. The estimated h can be used to compute the internal variable $z(t)$. It then becomes relatively easy to estimate the nonlinear function $g(\cdot)$ from the computed $z(t)$ and the measured $y(t)$.

Other Block-Oriented Model Structures

Among block-oriented models composed of more blocks, the most well-known ones concern Hammerstein-Wiener system and Wiener-Hammerstein system. They are both composed of three blocks connected in series, the former has a linear dynamic block preceded and followed by two nonlinear static blocks, and the latter has a nonlinear static block in the middle of two linear dynamic blocks. In general, the prediction error method (PEM) (Ljung 1999) is applied to the identification of such systems, with heuristic methods for the initialization of model parameters. Some recent results on Hammerstein-Wiener system identification have been reported in Wills et al. (2013). There exist also some other variants, with parallel blocks (Adil et al. 2018) or feedback loops (Xiao et al. 2018). In most cases, each block is either *linear dynamic* or *nonlinear static*, but there is a notable exception: *hysteresis* blocks. Hysteresis is a phenomenon typically observed in some magnetic or mechanic systems. Its mathematical description is both dynamic and strongly nonlinear and cannot be decomposed into linear dynamic and nonlinear static blocks. Due to the importance of hysteresis components in some control systems, system identification involving such blocks is still an active research topic.

LPV Models

Linear parameter-varying (LPV) models could be classified as black-box models, because typically they rely more on experimental data than on prior knowledge. However, engineers often have good insights into such models; they are thus presented in the gray-box section.

From Gain Scheduling to LPV Models

Gain scheduling is a method originally developed for the control of nonlinear systems. It consists in designing different controllers for different working points of a nonlinear system and in switching among the designed controllers according to the actual working point. It is typically assumed that the working point is determined by some observed variable (vector) referred to as the *scheduling variable* and denoted by ρ . Around each considered working point, the nonlinear system is linearized so that the corresponding controller can be designed from the linear control theory. A by-product of this controller design procedure is a collection of linearized models indexed by the scheduling variable ρ . This collection, seen as a whole model of the globally nonlinear system, is known as an LPV model (Toth 2010). This approach has been particularly successful in the field of flight control.

An LPV model can be formulated either in input-output form or in state-space form. In the input-output form, a SISO model can be written as

$$\begin{aligned} y(t) &+ a_1(\rho) y(t-1) + \dots + a_{n_a}(\rho) y(t-n_a) \\ &= b_1(\rho) u(t-1) + \dots \\ &+ b_{n_b}(\rho) u(t-n_b) + v(t) \end{aligned} \quad (8)$$

and in the state-space form as

$$x(t+1) = A(\rho)x(t) + B(\rho)u(t) + w(t) \quad (9a)$$

$$y(t) = c(\rho)x(t) + D(\rho)u(t) + v(t) \quad (9b)$$

As a global model of the whole nonlinear system, the ρ -dependent parameters (matrices) $a_i(\rho)$, $b_j(\rho)$, $A(\rho)$, etc. are functions defined for all $\rho \in \Omega$, where Ω is the relevant working range of the considered system (a compact subset of a real vector space). If originally the LPV model was built through a collection of linearized models around different working points, then the values of these functions are first defined for the corresponding discrete values of ρ . For other

values of $\rho \in \Omega$, these functions can be defined by interpolation. The interpolation of state-space models is a nontrivial problem (Zhang and Ljung 2017). Alternatively, by choosing some parametric forms of $a_i(\rho)$, $b_j(\rho)$, $A(\rho)$, etc., the whole LPV model can also be estimated by fitting it to a data set Z^N , through nonlinear optimization (Toth 2010).

Local Linear Models

In an LPV model, the model parameters can in principle depend on the scheduling variable ρ in any chosen manner. A particularly useful case is when they are formulated as expansions over local basis functions. For example, in (8), the parameter $a_i(\rho)$ may be expressed as

$$a_i(\rho) = \sum_{l=1}^m a_{i,l} \kappa_l(\rho) \quad (10)$$

where $\kappa_l(\cdot)$ are some chosen bell-shaped (local) basis functions, typically the Gaussian function, centered at different positions $\rho = c_l \in \Omega$, and $a_{i,l}$ are coefficients of the expansion. Similarly

$$b_j(\rho) = \sum_{l=1}^m b_{j,l} \kappa_l(\rho). \quad (11)$$

Assume that the basis functions are normalized such that

$$\sum_{l=1}^m \kappa_l(\rho) = 1 \quad (12)$$

for all $\rho \in \Omega$. Then the LPV model (8) can be viewed as an interpolation of m “local” models

$$\begin{aligned} y(t) &+ a_{1,l} y(t-1) + \dots + a_{n_a,l} y(t-n_a) \\ &= b_{1,l} u(t-1) + \dots + b_{n_b,l} u(t-n_b) + v(t) \end{aligned} \quad (13)$$

indexed by $l = 1, 2, \dots, m$. Each of these linear models is valid for ρ close to c_l , the center of the corresponding basis function $\kappa_l(\cdot)$; hence, they are called *local linear models*.

If the local basis functions $\kappa_l(\rho)$ are viewed as *membership functions* of fuzzy sets, then the local linear model is strongly related to the Takagi-Sugeno fuzzy model (Takagi and Sugeno 1985).

An advantage of this point of view is the possibilities of incorporating prior knowledge in the form of linguistic rules and of interpreting some local linear models resulting from system identification.

There are two approaches to building local linear models. The first one is the local approach: for each chosen value of $c_l \in \Omega$, a local model is estimated from data corresponding to the values of ρ within a neighborhood of c_l . This approach has the advantages of being computationally efficient, easily updatable, and well understood by engineers. The second one is the global approach: all the model parameters are estimated simultaneously by solving a single optimization problem for the whole model. This approach can produce more accurate models in terms of prediction error, but it is numerically much more expensive and may lead to models difficult to be interpreted by engineers.

The practical success of local linear models strongly depends on the possibility of finding a scheduling variable ρ of small dimension relevantly determining the working point of the considered system. If there exists a nonlinear state-space model of the system, then in principle the working point is determined jointly by the state and the input of the system. As quite often physically meaningful state variables are not fully observed, they cannot be used in the definition of ρ . It is possible to define ρ as delayed output and input variables, e.g.,

$$\rho^T = [y(t), \dots, y(t-n_a), u(t-1), \dots, u(t-n_b)]$$

but it typically leads to a vector of quite large dimension (Wang et al. 2017). It is thus important to use practical insights about a given system to find a relevant vector ρ of reduced dimension.

For a single-dimensional ρ , the choice of the local basis function centers c_l can be made following some practical insight or equally spaced within Ω . For a large-dimensional ρ , this task is more difficult. The equally spaced approach would lead to too many local models, as their number would exponentially increase with the dimension of ρ . In this case, an empirical approach, called *local linear model*

tree (LOLIMOT) (Nelles 2001), can be applied. It iteratively partitions Ω in order to place the local basis functions where the system is more likely nonlinear or where the available data are more concentrated.

Black-Box Models

Ideally speaking, a black-box model should be solely built from experimental data, without any prior knowledge. In practice, some prior knowledge is always necessary, though experimental data play a much more important role. For instance, the choice of the input and output variables, implying a causality relationship, involves some important prior knowledge.

With the fast development of electronic devices, more and more sensor signals are available in various fields, notably for engineering, environmental, and biomedical systems. Meanwhile, the processing power of modern computers increases every year. Black-box modeling has thus more and more potential applications. Nevertheless, the importance of prior knowledge in a modeling procedure should not be forgotten. In general prior knowledge leads to more reliable models in terms of validity range, as the validity of physical equations is often well understood. In contrast, for a black-box model essentially based on experimental data, it may be hard to ensure its validity for interpolation and even harder for extrapolation.

Input-Output Black-Box Models

As the primary role of a mathematical model is to predict the output of the system for given input values, it is natural to design black-box models directly in the form of a predictor. As the output $y(t)$ of a dynamic system depends on the past inputs, a predicted output $\hat{y}(t)$ may be formulated in the form of

$$\hat{y}(t) = f(u(t-1), u(t-2), \dots, u(t-n_b)) \quad (14)$$

where $f(\cdot)$ is some nonlinear function (to be estimated from experimental data) and n_b is a chosen integer. In principle, n_b can be infinitely

large (as $y(t)$ depends on *all* the past inputs in general), but in practice, a model of finite complexity has to be chosen. If the considered system is stable in the sense that sufficiently old past inputs are (gradually) forgotten, then it is reasonable to truncate the dependence on the past inputs.

The model structure (14) is similar to the linear finite impulse response (FIR) model (Ljung 1999). It is known that, for linear system identification, the use of ARX models, predicting $y(t)$ from both past inputs and past outputs, is often more efficient than FIR models, in the sense of requiring fewer model parameters. By analogy, the nonlinear ARX model takes the form

$$\hat{y}(t) = f(y(t-1), \dots, y(t-n_a), u(t-1), \dots, u(t-n_b)). \quad (15)$$

This nonlinear ARX model and some variants are likely the most frequently used black-box model structures for nonlinear dynamic system identification (Sjöberg et al. 1995; Juditsky et al. 1995; Billings 2013).

Nonlinear Function Estimators

For a nonlinear ARX model in the form of (15), the nonlinear function $f(\cdot)$ has to be estimated from an available input-output data set Z^N . Typically, an estimator of $f(\cdot)$ with some chosen parametric structure is used. Let

$$\phi^T(t) = [y(t-1), \dots, y(t-n_a), u(t-1), \dots, u(t-n_b)], \quad (16)$$

then system identification in this case amounts to solving a nonlinear regression problem

$$y(t) = g(\phi(t); \theta) + v(t) \quad (17)$$

where $g(\cdot)$ is a chosen nonlinear function parametrized by θ , capable of approximating a large class of nonlinear functions by appropriately adjusting θ , and $v(t)$ is the modeling error to be minimized in some sense.

The most well-known nonlinear function estimators implementing $g(\cdot)$ in practice are polynomials, splines, multiple-layer neural networks, radial basis networks, wavelets, and fuzzy-neural estimators. Most of these estimators can be written in the form

$$g(\phi(t); \theta) = \sum_{l=1}^m \gamma_l \kappa(\alpha_l(\phi - \beta_l)) \quad (18)$$

or in some close variant of this form, where $\kappa(\cdot)$ is some “mother” basis function dilated and translated by α_l and β_l before being weighted by γ_l in the sum forming the estimator (Sjöberg et al. 1995). For example, $\kappa(\cdot)$ is typically chosen as a (Gaussian) bell-shaped function in radial basis networks or a sigmoid (S-shaped) function in some multiple-layer neural networks.

Another approach to nonlinear function estimation is called *nonparametric estimation*. Its main idea is to estimate $f(\varphi^*)$ for any given value of φ^* by the (weighted) average of the values of $y(t)$ in the available data set corresponding to values of $\varphi(t)$ close to φ^* . This category includes *kernel* estimators (Nadaraya 1964) and *memory-based* estimators (Specht 1991).

The nonlinear function estimation problem as formulated in (17) can also be addressed with the Gaussian process model. Assume that g in (17) is a Gaussian process whose covariance matrix for any regressor pair $\varphi(t)$ and $\varphi(\tau)$ is a known function of the regressor pair, then the posterior distribution of g given observations on $y(t)$ can be computed by applying the Bayes’ theorem under certain assumptions (Rasmussen and Williams 2006). This method is strongly related to the least squares support vector machines (Suykens et al. 2002) and to some extent is similar to kernel estimators.

The difficulty for estimating a nonlinear function $f(\varphi)$ strongly depends on the dimension of φ . In the single-dimensional case, most existing methods can produce satisfactory results. When the dimension of φ , say n , increases, in order to keep the data “density” unchanged, the number of data points must increase exponentially with n . This fact implies that, in the high-dimensional

case (say $n > 10$), for most practically available data sets, the data points are sparse in the space of φ . It is thus practically impossible to estimate $f(\varphi)$ with a good accuracy everywhere in the space of φ . In order to remedy this problem, prior knowledge can be used to form a more elaborated vector φ of reduced dimension, instead of the simple form of past input and output variables. The resulting model will be more of gray-box nature. Recently, there have been attempts using *tensor networks* to reduce the complexity of nonlinearity estimators (Batselier et al. 2017; Gunes et al. 2018). A more direct approach is to expect that estimation algorithms automatically discover some low-dimension nature of the nonlinear relationship being estimated. The success would depend on the suitability of the chosen particular nonlinear function estimator for the considered system. This problem is strongly related to studies in machine learning (Pillonetto et al. 2014). The recent progress in deep learning has naturally inspired new studies in nonlinear system identification (De la Rosa and Yu 2016; Yu and Pacheco 2018; Woo et al. 2018).

State-Space Black-Box Models

For a gray-box model in the form of (1) and (2), it is assumed that the parametric forms of the nonlinear functions $f(\cdot)$ and $h(\cdot)$ are known from prior knowledge. If no such knowledge is available, it is possible to estimate these nonlinear functions with some function estimator, like those introduced in the previous subsection. Such an approach leads to state-space black-box models. In practice, it is easier to use the discrete-time counterpart of the state equation (1). Because typically the state vector $x(t)$ is not directly observed, the estimation of $f(\cdot)$ and $h(\cdot)$ cannot be formulated as nonlinear regression problems, in contrast to the case of input-output black-box models. Another difficulty is related to the nonuniqueness of the state-space representation of a given system: any (linear or nonlinear) state transformation would lead to a different state-space representation of the same system. In some existing methods, a linear state-space model is first estimated; then nonlinear function estimators

are used to compensate the residuals of $f(\cdot)$ and $h(\cdot)$ after their linear approximations (Paduart et al. 2010).

Multiple-Input Multiple-Output Systems

For multiple-input multiple-output (MIMO) systems, state-space models like (1)–(2) remain in the same form, by considering vector values of the notations $u(t)$ and $y(t)$ at each time instant, up to some similar adaptation of the other involved notations. For input-output models like (15), the involved notations can also be vector valued, but the fact that different inputs and/or outputs can have different delays makes the notations more complicated. For block-oriented models, though a MIMO linear block is usually described by a general linear model in state-space form or in input-output form, there seems no consensus for the structural choice of MIMO nonlinear blocks.

Some Practical Issues

The general practical aspects discussed in ► [System Identification: An Overview](#) are of course also valid for nonlinear system identification, but some particularities in the nonlinear case should be highlighted here.

It is important to apply appropriate input signals so that the collected data convey sufficient information for system identification. The design of input signals for this purpose is known as *experiment design*. In the framework of linear system identification, experiment design is usually formulated through the optimization of the covariance matrix of model parameter estimates (► [Experiment Design and Identification for Control](#)), which often leads to non-convex optimization problems. Experiment design in the nonlinear case has not been systematically studied. If possible, the chosen input signal should be similar to what will be actually applied to the considered system and cover various working conditions. Another simple rule is that the input should excite a nonlinear system at different amplitudes,

whereas binary input signals are often used for linear systems.

Model validation is a particularly delicate task for nonlinear black-box models. As already mentioned when such models were introduced, the available data points are usually sparse when a nonlinear function is estimated in a high-dimensional space; it is thus practically impossible to uniformly ensure the estimation accuracy of the nonlinear function. It is important to extensively perform *cross-validation*, by testing the validity of the model on large data sets that have not been used for model estimation.

Regularization is also an important issue for nonlinear black-box models. Because of lack of prior knowledge, each nonlinear black-box model has a flexible structure in order to cover a large class of nonlinear systems, typically with many model parameters, implying large variances of parameter estimates (► [System Identification: An Overview](#)). Appropriately applying a regularized criterion for model parameter estimation can reduce the variances (► [System Identification Techniques: Convexification, Regularization, Relaxation](#)). For gray-box models, prior knowledge can be used for regularization through a Bayesian approach, but this approach is not applicable to black-box models.

Summary and Future Directions

Compared to linear system identification, the nonlinear case is a much more vast topic, of which this entry provides only a rough overview. The main lines that should be retained are that both prior knowledge and experimental data are required for system identification, and that the more prior knowledge is incorporated in a model, the better the extent of its validity is understood. The lack of prior knowledge should be compensated by the processing of large amounts of data. The data that can be processed within an acceptable time depend on the power of computers that progresses every year. Meanwhile, the research and development

of efficient algorithms for large data processing with multiple or massively parallel processors are an exciting topic for system identification.

Nonlinear Zero Dynamics

Alberto Isidori
Department of Computer and System Sciences
“A. Ruberti”, University of Rome “La
Sapienza”, Rome, Italy

Abstract

The notion of zero dynamics plays a role in nonlinear systems that is analogous to the role played, in a linear system, by the notion of zeros of the transfer function. In this article, we review the basic concepts underlying the definition of zero dynamics and discuss its relevance in the context of nonlinear feedback design.

Keywords

High-gain feedback · Inverse systems · Minimum-phase nonlinear systems · Normal forms · Output regulation · Stabilization

Introduction

The concept of zero dynamics of a nonlinear system was introduced in the early 1980s as the nonlinear analogue of the concept of transmission zero of a linear system. This concept played a fundamental role in the development of systematic methods for asymptotic stabilization of relevant classes of nonlinear systems. As a matter of fact, a nonlinear system in which the zero dynamics possess a globally asymptotically stable equilibrium can be robustly stabilized, globally or at least with guaranteed region of attraction, by means of output feedback. This is a nonlinear analogue of a well-know property of linear systems, namely, the property that an n -dimensional linear systems having $n - 1$ zeros with negative real part can be stabilized by means of proportional output feedback, if the feedback gain is sufficiently large. The concept of zero dynamics also plays a relevant role in variety of other problems of feedback design, such as input-output linearization with internal stability, non-interacting control with internal stability, output regulation, and feedback equivalence to passive systems.

The Zero Dynamics

One of the cornerstones of the geometric theory of control systems (for linear as well as for nonlinear systems) is the analysis of how the observability property can be influenced by feedback. This study, originally conceived in the context of the problem of disturbance decoupling, had far reaching consequences in a number of other domains. One of these consequences is the possibility of characterizing in “geometric terms” the notion of *zero* of the transfer function of a system. In a (single-input single-output and

minimal) linear system, a complex number z is a zero of the transfer function if and only if the input $u(t) = \exp(zt)$ yields – for a suitable choice of the initial state – a forced response in which the output is identically zero. This “open-loop” and “time-domain” characterization has a “closed-loop and “geometric” counterpart: all such z ’s coincide with the eigenvalues of the unobservable part of the system, once the latter has been rendered maximally unobservable by means of feedback. One of the earlier successes of the geometric approach to the analysis and design of nonlinear systems was the possibility of extending these equivalent characterizations to the domain of nonlinear systems.

To see how this is possible, consider for simplicity the case of a system modeled by equations of the form

$$\begin{aligned}\dot{x} &= f(x) + g(x)u \\ y &= h(x)\end{aligned}$$

with state $x \in \mathbb{R}^n$, input $u \in \mathbb{R}$, output $y \in \mathbb{R}$ and in which $f(x), g(x), h(x)$ are smooth functions. Systems of this forms are called *input-affine systems*. The analysis of such systems is rendered particularly simple if appropriate notations are used. Given any real-valued smooth function $\lambda(x)$ and any n -vector valued smooth function $X(x)$, let $L_X \lambda(x)$ denote the (directional) derivative of $\lambda(x)$ along $X(x)$, that is the real-valued smooth function

$$L_X \lambda(x) = \sum_{i=1}^n \frac{\partial \lambda}{\partial x_i} X_i(x),$$

and, recursively, set $L_X^d \lambda = L_X L_X^{d-1} \lambda(x)$ for any $d \geq 1$.

Suppose there exists an integer $r \geq 1$ with the following properties

$$\begin{aligned}L_g h(x) &= L_g L_f h(x) = \cdots = L_g L_f^{r-2} h(x) \\ &= 0 \quad \forall x \in \mathbb{R}^n \\ L_g L_f^{r-1} h(x) &\neq 0 \quad \forall x \in \mathbb{R}^n.\end{aligned}$$

If this is the case, it is possible to show that the set

$$\begin{aligned}Z^* &= \{x \in \mathbb{R}^n : h(x) = L_h(x) = \cdots \\ &= L_f^{r-1} h(x) = 0\}\end{aligned}$$

is a smooth sub-manifold of $\mathbb{R}^n$, of codimension r . It is also easy to show that the state-feedback law

$$u^*(x) = -\frac{L_f^r h(x)}{L_g L_f^{r-1} h(x)}$$

renders the vector

$$f^*(x) = f(x) + g(x)u^*(x)$$

tangent to Z^* , at each point x of Z^* . In other words, Z^* is an *invariant* manifold of the feedback-modified system

$$\dot{x} = f^*(x).$$

It is seen from this construction that the output $y(t) = h(x(t))$ of the system is identically zero if and only if $x(0) \in Z^*$ and $u(t) = u^*(x(t))$, where $x(t)$ is the solution of $\dot{x} = f^*(x)$ passing through $x(0)$ at time $t = 0$. As a consequence, the *restriction* of $\dot{x} = f^*(x)$ to its invariant manifold Z^* characterizes all *internal* dynamics that occur in the system once initial condition and input are chosen in such a way that the output is constrained to be identically zero. The dynamics in question are called the *zero-dynamics* of the system. Note that this construction demonstrates, as anticipated, the equivalence between an “open-loop” and a “closed-loop” characterization of all the (internal) dynamics of a given system that are compatible with the constraint that the output is identically zero. This construction can be extended to multi-input multi-output systems, with the aid of an appropriate recursive algorithm, known as the *zero dynamics algorithm* (Isidori 1995).

Normal Forms

The coordinate-free construction presented above becomes even more transparent if special coordi-

nates are chosen. To this end, set

$$g^*(x) = \frac{1}{L_g L_f^{r-1} h(x)} g(x)$$

and define, recursively,

$X_0(x) = g^*(x)$, $X_k(x) = [f^*(x), X_{k-1}(x)]$, for $1 \leq k \leq r-1$, in which $[Y(x), X(x)]$ denotes the Lie bracket of $Y(x)$ and $X(x)$. It is possible to show that if the vector fields $X_0(x), \dots, X_{n-1}(x)$ are *complete*, there exists a smooth nonlinear, *globally defined*, change of variables by means of which the system can be transformed into a system of the form

$$\begin{aligned} \dot{z} &= f_0(z, \xi) \\ \dot{\xi} &= A_r \xi + B_r [q_0(z, \xi) + b(z, \xi)u] \\ y &= C_r \xi \end{aligned}$$

in which $z \in \mathbb{R}^{n-r}$, $\xi \in \mathbb{R}^n$, the matrices A_r, B_r, C_r have the form

$$\begin{aligned} A_r &= \begin{pmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & \dots & 1 \\ 0 & 0 & 0 & \dots & 0 \end{pmatrix}, \quad B_r = \begin{pmatrix} 0 \\ 0 \\ \cdot \\ 0 \\ 1 \end{pmatrix}, \\ C_r &= (1 \ 0 \ 0 \ \dots \ 0), \end{aligned}$$

and $b(z, \xi) \neq 0$ for all (z, ξ) . These equations are said to be in *normal form* (Isidori 1995).

It is easy to check that, in these coordinates, the manifold Z^* is the set of all pairs (z, ξ) having $\xi = 0$, the state feedback law $u^*(x)$ is the function

$$u^*(z, \xi) = -\frac{q_0(z, \xi)}{b(z, \xi)}$$

and the restriction of $\dot{x} = f^*(x)$ to the manifold Z^* is nothing else than

$$\dot{z} = f_0(z, 0).$$

The latter provide a simple characterization of the zero dynamics of the system, once that the latter has been brought to its normal form.

It is worth observing that, in the case of a linear system, functions $f_0(z, \xi)$ and $q_0(z, \xi)$ are linear functions, and $b(z, \xi)$ is a constant. Consequently, the normal form can be written as

$$\begin{aligned} \dot{z} &= Fz + G\xi \\ \dot{\xi} &= A_r \xi + B_r [Hz + K\xi + bu] \\ y &= C_r \xi. \end{aligned}$$

It is also easy to check that the transfer function of the system can be expressed as

$$T(s) = b \frac{\det(sI - F)}{\det(sI - A)},$$

in which

$$A = \begin{pmatrix} F & G \\ B_r H & A_r + B_r K \end{pmatrix}.$$

From this it is concluded that in a (controllable and observable) linear system, the zeros of the transfer function $T(s)$ coincide with the eigenvalues of F . In other words, in a linear system the zero dynamics are linear dynamics whose eigenvalues coincide with the zeros of the transfer function of the system.

The Inverse System

Another property associated with the notion of zero of the transfer function, in a (single-input single-output) linear system, is the fact that the zeros characterize the dynamics of the inverse system (the latter being – loosely speaking – a system able to reproduce the input $u(t)$ from output $y(t)$ that this input has generated). This property has an immediate analogue for nonlinear systems. Considering system in normal form and setting

$$\mathbf{y}^{r-1}(t) = \text{col}(y(t), y^{(1)}(t), \dots, y^{(r-1)}(t)),$$

it is easily seen that the input $u(t)$ can be determined as the output of a dynamical system, driven by $\mathbf{y}^{r-1}(t)$ and $\mathbf{y}^{(r)}(t)$, modeled by

$$\begin{aligned}\dot{z} &= f_0(z, \mathbf{y}^{r-1}) \\ u &= \frac{\mathbf{y}^{(r)} - q_0(z, \mathbf{y}^{r-1})}{b(z, \mathbf{y}^{r-1})}.\end{aligned}\quad (1)$$

Thus, it is concluded that the unforced internal dynamics of the inverse system coincide with the zero dynamics as defined above.

It should be stressed, though, that the coincidence is limited to the case of single-input single-output systems. For a multi-input multi-output nonlinear systems, the link between zero dynamics and the dynamics of the inverse system is more subtle. This is essentially due to the fact that while the concept of zero dynamics only seeks to determine the dynamics compatible with the constraint that the output is identically zero, the inverse system must describe all dynamics resulting in *any* admissible output function. As a consequence, computation of the zero dynamics and computation of the inverse system (whenever this is possible) are not equivalent and the latter is possible only under substantially stronger assumptions. The computation of the zero dynamics is based on an extension (Isidori 1995) of the classical algorithm of Wonham (1979) for the computation of the largest controlled invariant subspace in the kernel of the output map, while the computation of the inverse system is based on extensions, due to Hirschorn (1979) and Singh (1981) of the so-called structure algorithm introduced by Silverman (1969) for the computation of inverses and zero structure at the infinity. For a comparison of such assumptions and of their influence on the outcome of the associated algorithms, see Isidori and Moog (1988).

Input-Output Linearization

An appealing feature of the normal form described above is the straightforward observation that a (state) feedback law of the form

$$u = \frac{1}{b(z, \xi)} [-q_0(z, \xi) + K_r \xi + v]$$

changes the system into a system

$$\begin{aligned}\dot{z} &= f_0(z, \xi) \\ \dot{\xi} &= (A_r + B_r K_r) \xi + B_r v \\ y &= C_r \xi\end{aligned}$$

whose input-output behavior (between input v and output y) is *fully linear* (and stable if K_r is chosen so that the matrix $A_r + B_r K_r$ in Hurwitz). In fact, the law in question renders the system partially unobservable, with all nonlinearities confined to its unobservable part (Isidori et al. 1981). This control law is clearly non-robust, as it relies upon exact cancelation of possibly uncertain terms, but it can be rendered robust by means of appropriate dynamic compensation (Freidovich and Khalil 2008).

The system obtained in this way has the structure of a cascade of two sub-systems, one of which, modeled as

$$\dot{z} = f_0(z, \xi),$$

is seen as “driven” by the input ξ . This motivates the interest in classifying the asymptotic properties of such subsystem, as discussed below.

Asymptotic Properties of the Zero Dynamics

Linear systems with no zeroes in the right-half complex plane are traditionally called *minimum-phase* systems, in view of certain properties of the Bode gain and phase plots of its transfer function. Thus, in view of the interpretation given above, linear systems whose zero dynamics are asymptotically stable are minimum-phase systems. This terminology has been (somewhat abusively, but with the clear intent of providing a concise and expressive characterization) borrowed to classify nonlinear systems whose zero dynamics have desirable (from the stability viewpoint) properties. Assuming that $z = 0$ is an equilibrium of

$\dot{z} = f_0(z, 0)$, the following cases are considered:

- A nonlinear system is *locally minimum-phase* (respectively, *locally exponentially minimum-phase*) if the equilibrium $z = 0$ of $\dot{z} = f_0(z, 0)$ is locally asymptotically (respectively locally exponentially) stable (Byrnes and Isidori 1984).
- A nonlinear system is *globally minimum-phase* if the equilibrium $z = 0$ of $\dot{z} = f_0(z, 0)$ is globally asymptotically stable (Byrnes and Isidori 1991).
- A nonlinear system is *strongly minimum-phase* if the system $\dot{z} = f_0(z, \xi)$, viewed as a system with input ξ and state z , is input-to-state stable (Liberzon 2002).

According to the well-known criterion of Sontag (1995) for input-to-state stability, a system is strongly minimum phase if and only if there exists a positive definite and proper smooth real-valued function $V(z)$, class $\mathcal{K}_\infty$ functions $\underline{\alpha}(\cdot), \bar{\alpha}(\cdot), \alpha(\cdot)$ and a class $\mathcal{K}$ function $\chi(\cdot)$ satisfying

$$\begin{aligned} \underline{\alpha}(|z|) &\leq V(z) \leq \bar{\alpha}(|z|) \quad \forall z \\ \frac{\partial V}{\partial z} f_0(z, \xi) &\leq -\alpha(|z|) \quad \forall (z, \xi) \\ \text{such that } |z| &\geq \chi(|\xi|). \end{aligned}$$

As a special case, it is seen that a system is globally minimum phase if and only if there exists a function $V(z)$, bounded as above, such that

$$\frac{\partial V}{\partial z} f_0(z, 0) \leq -\alpha(|z|) \quad \forall z.$$

If, instead, the weaker inequality

$$\frac{\partial V}{\partial z} f_0(z, 0) \leq 0 \quad \forall z$$

holds, the system is said to be *globally weakly minimum-phase*.

The criterion summarized above is of paramount importance in the design of feedback laws to the purpose of stabilizing nonlinear

systems that are globally (or strongly) minimum phase, as it will be seen below.

Zero Dynamics and Stabilization

The first and foremost immediate implication of the properties described above is the fact that the feedback law

$$u = \frac{1}{b(z, \xi)} [-q_0(z, \xi) + K_r \xi],$$

if K_r is chosen so that the matrix $A_r + B_r K_r$ in Hurwitz, globally asymptotically stabilizes the equilibrium $(z, \xi) = (0, 0)$ of a strongly minimum-phase system. In fact, as observed, the corresponding closed-loop system can be seen as an asymptotically stable (linear) system driving an input-to-state stable (nonlinear) system. As already observed, this control mode is non-robust (as it relies upon exact cancelations) and requires the availability of the full state (z, ξ) of the controlled system. However, both these deficiencies can be to some extent fixed, by means of appropriate techniques, that will be briefly reviewed below.

If the requirement of global stability is replaced by the (weaker) requirement of *stability with a guaranteed region of attraction*, then the desired control goal can be achieved by means of a much simpler law, depending only on the partial state ξ and not requiring cancelations. Stability with a guaranteed region of attraction essentially means that a given equilibrium is rendered asymptotically stable, with a region of attraction that contains an a priori *fixed* compact set. In this context, the most relevant results can be summarized as follows.

Assume the system possesses a globally defined normal form and, without loss of generality, let $b(z, \xi) > 0$. Let the system be controlled by a “partial state” feedback of the form

$$u = -k K_r \xi,$$

in which $k \in \mathbb{R}$. Under this control mode, the following results are obtained:

- Suppose the system is strongly minimum phase. Then, there is a matrix K_r and, for every choice of a compact set $\mathcal{C}$ and of a number $\varepsilon > 0$, there are a number k^* and a time T^* such that, if $k \geq k^*$, all trajectories of the closed-loop system with initial condition in $\mathcal{C}$ are bounded and satisfy $|x(t)| \leq \varepsilon$ for all $t \geq T^*$.
- Suppose the system is strongly minimum phase and also locally exponentially minimum phase. Suppose $q_0(0, 0) = 0$. Then, there is a matrix K_r and, for every choice of a compact set $\mathcal{C}$ there is a number k^* such that, if $k \geq k^*$, the equilibrium $x = 0$ of the system is locally asymptotically stable, with a domain of attraction that contains the set $\mathcal{C}$.

In these results, the system is stabilized by means of a *static* control law that depends only on the partial state ξ and not on the (possibly unknown) quantities $q_0(z, \xi)$, $b(z, \xi)$. Bearing in mind the fact that the r components of ξ coincide with the output y and its derivatives $y^{(1)}, \dots, y^{(r-1)}$, it is possible to replace the control in question by means of a *dynamic* control law that only depends on the output y , following a design paradigm originally proposed by H. Khalil. In fact, if the system is strongly minimum phase and also locally exponentially minimum phase and if $q_0(0, 0) = 0$, asymptotic stability with a guaranteed region of attraction can be achieved by means of dynamical feedback law of the form Khalil and Esfandiari (1993)

$$\begin{aligned}\dot{\hat{\xi}}_1 &= \hat{\xi}_2 + \kappa c_{r-1}(y - \hat{\xi}_1) \\ \dot{\hat{\xi}}_2 &= \hat{\xi}_3 + \kappa^2 c_{r-2}(y - \hat{\xi}_1) \\ &\dots \\ \dot{\hat{\xi}}_{r-1} &= \hat{\xi}_r + \kappa^{r-1} c_1(y - \hat{\xi}_1) \\ \dot{\hat{\xi}}_r &= \kappa^r c_0(y - \hat{\xi}_1) \\ u &= -\sigma_L(k K_r \hat{\xi}),\end{aligned}$$

in which κ and the c_i are design parameters and $\sigma_L(s)$ is a smooth saturation function, characterized as follows: $\sigma_L(s) = s$ if $|s| \leq L$, $\sigma_L(s)$

is odd and monotonically increasing, with $0 < \sigma'_L(s) \leq 1$, and $\lim_{s \rightarrow \infty} \sigma_L(s) = L(1 + c)$ with $0 < c \ll 1$. The number L is a design parameter also.

It is also possible to show that a suitable “extension” of this dynamic feedback law can be used to asymptotically recover the effects of the input-output linearizing law considered earlier. In this way, the lack of robustness intrinsically present in such control law is overcome (Freidovich and Khalil (2008)).

Output Regulation

The concept of zero dynamics plays a fundamental role in the problem of output regulation. The problem in question considers a controlled plant modeled by

$$\begin{aligned}\dot{x} &= f(w, x, u) \\ e &= h(w, x),\end{aligned}$$

in which u is the control input, w is a set of exogenous variables (command and disturbances), and e is a set of regulated variables. The exogenous variables are thought of as generated by an autonomous system

$$\dot{w} = s(w)$$

known as the *exosystem*. The problem is to design a (possibly dynamic) controller

$$\begin{aligned}\dot{x}_c &= f_c(x_c, e) \\ u &= h_c(x_c, e)\end{aligned}$$

driven by the regulated variable e , such that in the resulting closed-loop system all trajectories are ultimately bounded and $\lim_{t \rightarrow \infty} e(t) = 0$. The problem in question has been the object of intensive research in the past years. In what follows we limit ourselves to highlight the role of the concept of zero dynamics in this problem.

Assume that the set W where the exosystem evolves is compact and invariant and suppose a controller exists that solves the problem of output

regulation. Then, the associated closed-loop has a steady-state locus (see Isidori and Byrnes 2008), the graph of a possibly set-valued map defined on W . Suppose the map in question is single-valued, which means that for each given exogenous input function $w(t)$, there exists a *unique* steady-state response, expressed as $x(t) = \pi(w(t))$ and $x_c(t) = \pi_c(w(t))$. If, in addition, $\pi(w)$ and $\pi_c(w)$ are continuously differentiable, it is readily seen that

$$\begin{aligned} L_s \pi(w) &= f(w, \pi(w), \psi(w)) \\ 0 &= h(w, \pi(w)) \\ L_s \pi_c(w) &= f_c(\pi_c(w), 0) \\ \psi(w) &= h_c(\pi_c(w), 0) \end{aligned} \quad \forall w \in W.$$

The first two equations, introduced in Isidori and Byrnes (1990), are known as the *nonlinear regulator equations*. They clearly show that the graph of the map $\pi(w)$ is a manifold contained in the zero set of the output map e , rendered invariant by the control $u = \psi(w)$. In particular, the steady-state trajectories of the closed-loop system are trajectories of the *zero dynamics* of the controlled plant. The second two equations, on the other hand, interpret the ability, of the controller, to generate the feedforward input necessary to keep $e(t) = 0$ in steady-state. This is a nonlinear version of the well-known *internal model principle* of Francis and Wonham (1975).

Passivity

Consider a nonlinear input-affine system having the same number m of inputs and outputs and recall that this system is said to be *passive* if there exists a continuous nonnegative function real-valued function $W(x)$, with $W(0) = 0$, that satisfies

$$W(x(t)) - W(x(0)) \leq \int_0^t y^T(s)u(s)ds$$

along trajectories. The function $W(x)$ is the so-called *storage function* of the system.

It is well known that the notion of passivity plays an important role in system analysis and

that the theory of passive systems leads to powerful methodologies for the design of feedback laws for nonlinear systems. In this context, the question of whether a given, non-passive, nonlinear system could be rendered passive by means of state feedback is indeed relevant. It turns out that this possibility can be simply expressed as a property of the zero dynamics of the system.

Suppose that $L_g h(x)$ is nonsingular and set $g^*(x) = g(x)[L_g h(x)]^{-1}$. If the m columns of $g^*(x)$ are complete and commuting vector fields, there exists a globally defined change of coordinates that brings the system in normal form

$$\begin{aligned} \dot{z} &= f_0(z, y) \\ \dot{y} &= q_0(z, y) + b(z, y)u \end{aligned}$$

Then, there exists a feedback law $u = \alpha(z, y)$ that renders the resulting closed-loop system passive, with a C^2 and positive definite storage function $W(x)$, if and only if the system is globally weakly minimum phase (Byrnes et al. 1991).

Limits of Performance

It is well-known that linear systems having zeros in the left-half plane are difficult to control, and obstruction exists to the fulfillment of certain control specifications. One of these is found in the analysis of the so-called *cheap control problem*, namely, the problem of finding a stabilizing feedback control that minimizes the functional

$$J_\varepsilon = \frac{1}{2} \int_0^\infty [y^T(t)y(t) + \varepsilon u^T(t)u(t)]dt$$

when $\varepsilon > 0$ is small. As $\varepsilon \rightarrow 0$, the optimal value J_ε^* tends to J_0^* , the *ideal performance*. It is well-known that, in a linear system, $J_0^* = 0$ if and only if the system is minimum phase and right invertible and, in case the system has zeros with positive real part, it is possible to express explicitly J_0^* in terms of the zeros in question. If the (linear) system is expressed in normal form as

$$\begin{aligned}\dot{z} &= Fz + G\xi \\ \dot{\xi} &= Hz + K\xi + bu \\ y &= \xi\end{aligned}$$

with $b \neq 0$, and the zero dynamics are antistable (that is *all* the eigenvalues of F have positive real part), it can be shown that J_0^* coincides with the minimal value of the energy

$$J = \frac{1}{2} \int_0^\infty \xi^T(t) \xi(t) dt$$

required to stabilize the (antistable) system $\dot{z} = Fz + G\xi$. In other words, the limit as $\varepsilon \rightarrow 0$ of the optimal value of J_ε is equal to the least amount of energy required to stabilize the dynamics of the inverse system.

This result has an appealing nonlinear counterpart (Seron 1999). In fact, for a nonlinear input-affine system having the same number m of inputs and outputs in normal form, with $f_0(z, \xi)$ of the form $f_0(z, \xi) = f_0(z) + g_0(z)\xi$ and $\dot{z} = f_0(z)$ antistable, under appropriate technical assumptions (mostly related to the existence of the solution of the associated optimal control problems), the same result holds: the lowest attainable value of the L_2 norm of the output coincides with the least amount of energy required to stabilize the dynamics of z .

Summary and Future Directions

The concept of zero dynamics plays an important role in a large number of problems arising in analysis and design of nonlinear control systems, among which the most relevant ones are the problems of asymptotic stabilization and those of asymptotic tracking/rejection of exogenous command/disturbance inputs. Essentially, all such applications deal with single-input single-output systems, require the system to be preliminarily reduced to a special form by means of appropriate change of coordinates, and assume the dynamics in question to be globally asymptotically stable. The analysis of systems having many inputs and many outputs, of systems in which normal forms cannot be defined, and of

systems in which the zero dynamics are unstable is still a challenging and unexplored area of research.

Nonparametric Techniques in System Identification

Rik Pintelon and Johan Schoukens
Department ELEC, Vrije Universiteit Brussel,
Brussels, Belgium

Abstract

This entry gives an overview of classical and state-of-the-art nonparametric time and frequency-domain techniques. In opposition to parametric methods, these techniques require no detailed structural information to get insight into the dynamic behavior of complex systems. Therefore, nonparametric methods are used in system identification to get an initial idea of the model complexity and for model validation purposes (e.g., detection of unmodeled dynamics). Their drawback is the increased variability compared with the parametric estimates. Although the main focus of this entry is on the classical identification framework (estimation of dynamical systems operating in open loop from known input, noisy output observations), the reader will also learn more about (i) the connection between transient and leakage errors, (ii) the estimation of dynamical systems operating in closed loop, (iii) the estimation in the presence of input noise, and (iv) the influence of nonlinear distortions on the linear framework. All results are valid for discrete- and continuous-time

systems. The entry concludes with some user choices and practical guidelines for setting up a system identification experiment and choosing an appropriate estimation method.

Keywords

Frequency response function · Noise (co) variances · Noise power spectrum · Correlation method · Gaussian process regression · Empirical transfer function estimate · Spectral analysis · Local polynomial method · Local rational method · Impulse transient response modeling method · Feedback · Errors-in-variables · Best linear approximation

Introduction

Nonparametric representations such as frequency response functions (FRFs) and noise power spectra are very useful in system identification: they are used (i) to verify the quality of the identification experiment (high or poor signal-to-noise ratio?), (ii) to get quickly insight into the dynamic behavior of the plant (complex or easy identification problem?), and (iii) to validate the parametric plant and noise models (detection of unmodeled dynamics); see also ► [“System Identification: An Overview”](#), by Lennart Ljung. In addition, via specially designed periodic excitation signals, it is possible to detect and quantify the nonlinear distortions in the FRF estimate. As such, without estimating a parametric model, the users can easily decide whether or not the linear framework is accurate enough for their particular application.

The estimation of the nonparametric models typically starts from sampled input-output signals $u(nT_s)$ and $y(nT_s)$, $n = 0, 1, \dots, N - 1$, that are transformed to the frequency domain via the discrete Fourier transform (DFT)

$$X(k) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} x(nT_s) e^{-j2\pi kn/N} \quad (1)$$

with T_s the sampling period, $x = u$ or y , and $X = U$ or Y . One of the main difficulties

in estimating an FRF and noise power spectrum is the leakage error in the DFT spectrum $X(k) = \text{DFT}(x(t))$ (1). It is due to the finite duration NT_s of the experiment, and it increases the mean square error of the nonparametric estimates. Therefore, all methods try to suppress the leakage error as much as possible.

This entry starts by a detailed analysis of the leakage problem (section “[The Leakage Problem](#)”), followed by an overview of standard and advanced nonparametric time (section “[Nonparametric Time-Domain Techniques](#)”) and frequency (section “[Nonparametric Frequency-Domain Techniques](#)”) domain techniques. First, it is assumed that the system operates in open loop (see Fig. 1) and that known input, noisy output observations are available (sections “[Nonparametric Time-Domain Techniques](#)” and “[Nonparametric Frequency-Domain Techniques](#)”). Next, section “[Extensions](#)” extends the results to systems operating in closed loop (section “[Systems Operating in Feedback](#)”); to noisy input, noisy output observations (section “[Noisy Input, Noisy Output Observations](#)”); and to nonlinear systems (section “[Nonlinear Systems](#)”). Finally, some user choices are discussed (section “[User Choices](#)”) and some practical guidelines are given (section “[Guidelines](#)”). Unless otherwise stated, the input $u(t)$ and the disturbing noise $v(t)$ are assumed to be statistically uncorrelated.

Nonparametric Techniques in System Identification, Fig. 1 Classical identification framework: discrete- or continuous-time plant operating in open loop; known input $u(t)$, noisy output $y(t)$ observations; and $v(t)$ filtered discrete-time or band-limited continuous-time white noise $e(t)$ that is independent of $u(t)$. $y_0(t)$ denotes the true output of the plant. In the continuous-time case, it is assumed that the unobserved driving noise source $e(t)$ has finite variance and constant (*white*) power spectrum within the acquisition bandwidth

The Leakage Problem

For arbitrary excitations $u(t)$, the relationship between the true input $U(k)$ and true output $Y_0(k)$ DFT spectra (1) of a linear dynamic system is given by

$$Y_0(k) = G(\Omega_k)U(k) + T_G(\Omega_k) \quad (2)$$

where $\Omega_k = j\omega_k$ or $\exp(-j\omega_k T_s)$ for, respectively, continuous- and discrete-time systems; $\omega_k = 2\pi k/(NT_s)$; $G(\Omega_k)$ the plant frequency response function; and $T_G(\Omega_k)$ the leakage error due to the plant dynamics (Pintelon and Schoukens 2012, Section 6.3.2). The leakage error $T_G(\Omega)$ is a smooth function of the frequency that decreases to zero as $O(N^{-1/2})$ for N increasing to infinity. It depends on the difference between the initial and final conditions of the experiment and has exactly the same poles as the plant transfer function. Therefore, the time-domain response of $T_G(\Omega)$ is decaying exponentially to zero as a transient error.

From this short discussion, it can be concluded that the leakage error in the frequency domain is equivalent to the transient error in the time domain. The only difference being that the former depends on the difference between the initial and final conditions, while the latter solely depends on the initial conditions.

Standard spectral analysis methods (see section “[Spectral Analysis Method](#)”) suppress the leakage term $T_G(\Omega_k)$ in (2) by multiplying the time-domain signals with a window $w(t)$ before taking the DFT (1)

$$(X(k))_W = \frac{1}{\sqrt{N}w_{\text{rms}}} \sum_{n=0}^{N-1} w(nT_s) x(nT_s) e^{-j2\pi \frac{kn}{N}} \quad (3)$$

with $w_{\text{rms}} = \left(\sum_{n=0}^{N-1} |w(nT_s)|^2 / N \right)^{1/2}$ the root mean square (rms) value of the window $w(t)$. The scaling in (3) is such that the transformation preserves the rms value of the signal. The relationship between the DFT spectra $(U(k))_W$ and

$(Y_0(k))_W$ of the windowed input-output signals $w(t)u(t)$ and $w(t)y_0(t)$ is given by

$$(Y_0(k))_W = G(\Omega_k) (U(k))_W + E_{\text{int}}(k) + E_{\text{leak}}(k) \quad (4)$$

where $E_{\text{int}}(k)$ and $E_{\text{leak}}(k)$ are, respectively, the interpolation error and the remaining leakage error

$$\begin{aligned} E_{\text{int}}(k) &= (G(\Omega_k)U(k))_W - G(\Omega_k) (U(k))_W \\ E_{\text{leak}}(k) &= (T_G(\Omega_k))_W \end{aligned} \quad (5)$$

Note that $E_{\text{int}}(k) = 0$ if $G(\Omega_k)$ is constant within the bandwidth of $W(k)$, while the interpolation error is large if the FRF varies significantly within the window bandwidth. To keep $E_{\text{int}}(k)$ small, the frequency resolution $1/(NT_s)$ should be sufficiently large and the window bandwidth should be small enough. On the other hand, a larger window bandwidth is beneficial for reducing the leakage error $E_{\text{leak}}(k)$. Hence, choosing an appropriate window for nonparametric FRF and noise power spectrum estimation is making a trade-off between the reduction of the leakage error $E_{\text{leak}}(k)$ and the increase of the interpolation error $E_{\text{int}}(k)$ (Schoukens et al. 2006).

Note that exactly the same analysis can be made for the continuous- or discrete-time dynamics of the disturbing output noise $v(t)$ in Fig. 1

$$V(k) = H(\Omega_k)E(k) + T_H(\Omega_k) \quad (6)$$

with $H(\Omega_k)$ the noise frequency response function, $E(k)$ the DFT of the unobserved driving discrete-time or band-limited continuous-time white noise source $e(t)$ (Pintelon and Schoukens 2012, Section 6.7.3), and $T_H(\Omega_k)$ the noise leakage (transient) term. The noise leakage term is often neglected but can be important for lightly damped systems (e.g., in modal analysis). Most nonparametric techniques suppress the sum of the plant and noise leakage errors $T_G(\Omega_k) + T_H(\Omega_k)$.

If an integer number of periods of the steady-state response to a periodic excitation is

measured, then the plant leakage error $T_G(\Omega_k)$ in (2) is zero, which simplifies significantly the estimation problem. Therefore, for the frequency-domain techniques, a distinction is made between periodic and nonperiodic excitations. Note, however, that the noise leakage (transient) term $T_H(\Omega_k)$ in (6) remains different from zero.

Nonparametric Time-Domain Techniques

The time-domain methods estimate the impulse response of the plant via the time-domain relationship that the true output $y_0(t)$ equals the convolution product between the impulse response $g(t)$ and the true input $u(t)$. For discrete-time systems, it takes the form

$$y_0(t) = \sum_{n=0}^{\infty} g(n)u(t-n) \quad (7)$$

In practice only a finite number of impulse response coefficients $g(t)$ can be estimated from N input-output samples, and, therefore, (7) is approximated by a finite sum

$$y_0(t) \approx \sum_{n=0}^L g(n)u(t-n) \quad (8)$$

where $L \leq N-1$ should also be determined from the data. From (8), it can be seen that the response depends on the past input values $u(-1), u(-2), \dots, u(-L)$. Since these values are unknown, an exponentially decaying transient error is present in the first L samples of the predicted output (8). This transient error is the time-domain equivalent of the leakage error $T_G(\Omega_k)$ in (2). To remove the transient error, the first L output samples can be discarded in the predicted output (8). It reduces the amount of data from N to $N-L$ and, hence, increases the mean square error of the estimates. If it is known that the transfer function has no direct term, then $g(0) = 0$, and the sum (8) starts from $n = 1$.

Correlation Methods

Correlation methods have been studied intensively since the end of the 1950s (see Eykhoff 1974) and are nowadays still used in telecommunication channel estimation and equalization. The impulse response coefficients are found by minimizing the sum of the squared differences between the observed output samples and the output samples predicted by (8)

$$\sum_{t=L}^{N-1} \left(y(t) - \sum_{n=0}^L g(n) u(t-n) \right)^2 \quad (9)$$

w.r.t. $g(m)$, $m = 0, 1, \dots, L$. The solution of this linear least squares problem is given by the famous Wiener-Hopf equation

$$\hat{R}_{yu}(m) = \sum_{n=0}^L g(n) \hat{R}_{uu}(m-n) \quad (10)$$

for $m = 0, 1, \dots, L$, where $\hat{R}_{yu}$ and $\hat{R}_{uu}$ are estimates of, respectively, the cross- and autocorrelation functions $R_{yu}(\tau) = \mathbb{E}\{y(t)u(t-\tau)\}$ and $R_{uu}(\tau) = \mathbb{E}\{u(t)u(t-\tau)\}$

$$\hat{R}_{yu}(m) = \frac{1}{N-L} \sum_{t=L}^{N-1} y(t)u(t-m) \quad (11)$$

$$\hat{R}_{uu}(m-n) = \frac{1}{N-L} \sum_{t=L}^{N-1} u(t-n)u(t-m) \quad (12)$$

(Godfrey 1993, Chapter 1; Ljung 1999; Chapter 6). Since the number of estimated impulse response coefficients L can grow with the amount of data N , the correlation method (10) is classified as being nonparametric. If the input is white noise, then the expected value of $\hat{R}_{uu}(m)$ is proportional to the Kronecker delta $\delta(m)$, and the cross-correlation $\hat{R}_{yu}(m)$ (10) is – within a scaling factor – a good approximation of the impulse response. This property is used in blind channel estimation.

Gaussian Process Regression

The linear least squares (9) solution can be (very) sensitive to disturbing output noise if L is not much smaller than N . This problem is circumvented by the Gaussian process regression approach. The key idea consists in modeling the impulse response coefficients $g(n)$ as a zero-mean Gaussian process with a certain covariance structure P_L that depends on a few hyper-parameters (Pillonetto et al. 2011). In Chen et al. (2012), it has been shown that the Gaussian process regression is equivalent to the following regularized linear least squares problem (see also ▶ “System Identification Techniques: Convexification, Regularization, Relaxation”), by Alessandro Chiuso

$$\sum_{t=L}^{N-1} \left(y(t) - \sum_{n=0}^L g(n)u(t-n) \right)^2 + \sigma^2 g^T P_L^{-1} g \quad (13)$$

where $g = (g(0), g(1), \dots, g(L))^T$ and with σ^2 the variance of the output disturbance. The hyper-parameters defining P_L and the noise variance σ^2 are estimated via an empirical Bayes method.

Nonparametric Frequency-Domain Techniques

The frequency-domain techniques estimate the frequency response function (FRF) using relationship (2) or (4) between the input-output DFT spectra. We start with the simplest approach and gradually increase the complexity of the estimation methods. Note that nonparametric FRF estimation is still a quickly evolving research area, such that the pros and cons of the advanced methods are yet not well established.

Empirical Transfer Function Estimation

If an integer number of periods P of the steady-state response to a *periodic excitation* is observed, then the leakage term in $T_G(\Omega_k)$ in (2) is zero, and the FRF is estimated by dividing the output by the input DFT spectra at the *excited frequencies* (Pintelon and Schoukens

2012, Section 2.4)

$$\hat{G}(\Omega_k) = \frac{Y(k)}{U(k)} \quad (14)$$

The output noise variance $\sigma_V^2(k)$ is estimated via the sample variance $\hat{\sigma}_V^2(k)$ of the output DFT spectra over the P consecutive signal periods. The variance of the FRF estimate (14) is then given by

$$\text{var}(\hat{G}(\Omega_k)) = \frac{\sigma_V^2(k)}{P |U(k)|^2} \quad (15)$$

where $|U(k)|$ is the magnitude of $U(k)$.

Applying (14) to *random excitations* gives the empirical transfer function estimate (Ljung 1999, Section 6.3). Due to the presence of the plant leakage error $T_G(\Omega_k)/U(k)$, the statistical properties of (14) for random inputs are quite different from those for periodic inputs. While the empirical transfer function estimate (ETF) is unbiased and has finite variance (15) for periodic inputs, it is biased and has infinite variance for random inputs (Broersen 2004). To improve the statistical properties of the ETF for random inputs, one can either approximate locally the ETF by a polynomial (Stenman et al. 2000) or perform a weighted average of ETFs over subrecords of the total response (Ljung 1999, Section 6.4). In Heath (2007), it is shown that the optimally (in mean square sense) weighted ETF equals the spectral analysis method.

Spectral Analysis Method

The spectral analysis method is available in any digital spectrum analyzer. It is based on the relationship between the FRF and the cross- and autopower spectra of the input-output signals

$$G(\Omega) = \frac{S_{yu}(\Omega)}{S_{uu}(\Omega)} = \frac{F\{R_{yu}(\tau)\}}{F\{R_{uu}(\tau)\}} \quad (16)$$

with $F\{\}$ the Fourier transform (Bendat and Piersol 1980, Chapter 4; Brillinger 1981, Chapter 8). Comparing (10) and (16), it can be seen that the spectral analysis method is the frequency-domain equivalent of the correlation method (take the

Fourier transform of the expected value of (10)). There are basically two methods for estimating the cross- and autopower spectra in (16) from sampled data: the Blackman and Tukey (1958) and the Welch (1967) procedures.

The Blackman-Tukey procedure (Blackman and Tukey 1958; Ljung 1999, Section 6.4) consists in taking the DFT (3) of the windowed cross- and autocorrelation functions, viz.,

$$\hat{R}_{yu}(\tau) = \frac{1}{N} \sum_{t=\tau}^{N-1} y(t) u(t-\tau) \quad (17)$$

$$\hat{S}_{Ryu}(k) = \frac{1}{\sqrt{N}} \sum_{\tau=0}^{N-1} w(\tau) \hat{R}_{yu}(\tau) e^{-j2\pi \frac{k\tau}{N}} \quad (18)$$

resulting in an FRF estimate (16) at the full frequency resolution $1/(NT_s)$ of the measurement. It can be shown that (18) is a smoothed version of the periodogram $Y(k)\overline{U(k)}$, where is $\bar{U}$ the complex conjugate of U (Brillinger 1981, Chapter 5).

In the Welch approach (Welch 1967; Pintelon and Schoukens 2012, Section 2.6), the N input-output samples are split into M subrecords of N/M samples each, and the DFT spectra $(U^{[m]}(k))_w$ and $(Y^{[m]}(k))_w$ of the windowed input and output samples are calculated via (3) where N is replaced by N/M , giving

$$\hat{S}_{Y_W U_W}(k) = \frac{1}{M} \sum_{m=1}^M (Y^{[m]}(k))_w \overline{(U^{[m]}(k))_w} \quad (19)$$

$$\hat{S}_{U_W U_W}(k) = \frac{1}{M} \sum_{m=1}^M \left| (U^{[m]}(k))_w \right|^2 \quad (20)$$

The spectral analysis estimate of the FRF and its variance are then given by

$$\hat{G}(\Omega_k) = \frac{\hat{S}_{Y_W U_W}(k)}{\hat{S}_{U_W U_W}(k)} \quad (21)$$

$$\text{var}(\hat{G}(\Omega_k)) \approx \frac{\sigma_V^2(k)}{M} \mathbb{E} \left\{ \hat{S}_{U_W U_W}^{-1}(k) \right\} \quad (22)$$

(Brillinger 1981, Chapter 8; Heath 2007). Finally, the output noise variance $\sigma_V^2(k)$ in (22) is estimated as

$$\hat{\sigma}_V^2(k) = \frac{M}{M-1} \left(\hat{S}_{Y_W Y_W}(k) - \frac{|\hat{S}_{Y_W U_W}(k)|^2}{\hat{S}_{U_W U_W}(k)} \right) \quad (23)$$

(Brillinger 1981, Chapter 8; Pintelon and Schoukens 2012, Section 2.5.4). Due to the spectral width of the window used, the estimates (21) and (23) are correlated over the frequency (the correlation length is about twice the spectral width). Note that (20) is used for estimating noise power spectra (Brillinger 1981, Chapter 5). Note also that for *periodic excitations* combined with a rectangular window $w(nT_s) = 1$, the spectral analysis estimate (21), where each subrecord is equal to a signal period, simplifies to the ETFE (14).

Compared with the Blackman-Tukey procedure (18), the FRF estimate (21) based on the Welch approach (19) and (20) has a frequency resolution and a variance (22) that are M times smaller. In measurement devices, the FRFs are estimated using the Welch approach (19)–(21) where each subrecord is an independent measurement with a fixed number of samples. The reason for this is that the cross- and autopower spectra estimates (19) and (20) can easily be updated as more experiments (input-output data records) are available. If the number of measured records M increases to infinity, then (21) converges to the true value, provided a perfect suppression of the leakage error.

In measurement devices, the quality of the spectral analysis estimate (21) is often quantified via the coherence $\gamma^2(\omega)$

$$\gamma^2(\omega) = \frac{|S_{yu}(\Omega)|^2}{S_{yy}(\Omega)S_{uu}(\Omega)} \quad (24)$$

which is comprised between 0 and 1. It is related to the variance of the spectral analysis estimate as

$$\text{var}(\hat{G}(\Omega_k)) = \frac{1 - \gamma^2(\omega_k)^2}{\gamma} (\omega_k) |G(\Omega_k)|^2$$

A coherence smaller than 1 indicates the presence of disturbing noise, residual leakage errors, non-linear distortions, or a nonobserved input.

Following the same lines of Welch (1967), the statistical properties of the spectral analysis estimate (21) can be improved via overlapping subrecords in the cross- and autopower spectra estimates (19) and (20). This has been studied in detail for noise power spectra in Carter and Nuttall (1980) and for FRFs in Antoni and Schoukens (2007).

Advanced Methods

The goal of the advanced methods is to estimate the FRF at the full frequency resolution $1/(NT_s)$ of the experiment duration NT_s while suppressing the influence of the leakage and the noise errors. Without some extra information, it is impossible to achieve this goal via (2). The additional piece of information that allows one to solve the problem is that the FRF and the leakage error are locally smooth functions of the frequency.

The *local polynomial method* (Pintelon and Schoukens 2012, Chapter 7) approximates the FRF and the leakage error in (2) locally in the frequency band $[k - n, k + n]$ by a polynomial. From the residuals of the local linear least squares solution, one also gets an estimate of the output noise variance σ_V^2 and, hence, also of the variance of the FRF. The whole procedure is repeated for all DFT frequencies k in the frequency band of interest. The correlation length of the estimates equals $\pm 2n$, which is twice the local bandwidth of the polynomial approximation.

The *local rational method* (McKelvey and Guérin 2012) follows the same lines as the local polynomial method, except that the FRF and the leakage error in (2) are locally approximated by rational forms with the same poles ($G = B/A$ and $T_G = I/A$). Due to the common poles, the local rational approximation problem can be transformed into a local linear least squares problem. The method is biased but suppresses better the plant leakage error of lowly damped systems.

The *transient impulse response modeling method* (Hägg and Hjalmarsson 2012) approximates the FRF and the leakage error by,

respectively, finite impulse and transient response models, giving a large sparse global linear least squares problem. From the residuals of the global linear least squares solution, one gets an estimate of the output noise variance σ_V^2 and, hence, also of the variance of the FRF. This approach has the best smoothing properties and is recommended in case the noise error is dominant.

Extensions

In sections “Nonparametric Time-Domain Techniques” and “Nonparametric Frequency-Domain Techniques,” it is assumed that the linear plant operates in open loop and that the input is known exactly. If the plant operates in feedback and/or the input observations are noisy, then the presented time and frequency-domain techniques are biased. In sections “Systems Operating in Feedback” and “Noisy Input, Noisy Output Observations,” it is shown that the estimation bias can be avoided if a known external reference signal is available (typically the signal stored in the arbitrary waveform generator).

Since most real-life systems behave to some extent nonlinearly, it is important to detect and quantify the nonlinear effects in FRF estimates. This issue is handled in section “Nonlinear Systems.”

Systems Operating in Feedback

The key difficulty of estimating the FRF of a plant operating in feedback (see Fig. 2) using *nonperiodic excitations* is that the true input $u(t)$ is correlated with the process noise $v(t)$. The direct

approaches of sections “Nonparametric Time-Domain Techniques” and “Nonparametric Frequency-Domain Techniques” lead to biased estimates (Wellstead 1981). This can easily be seen from the ETFE (14) applied to the feedback setup in Fig. 2

$$\hat{G}(\Omega_k) = \frac{G(\Omega_k)G_{\text{act}}(\Omega_k)R(k) + V(k)}{G_{\text{act}}(\Omega_k)R(k) - G_{\text{fb}}(\Omega_k)V(k)} \quad (25)$$

where $G_{\text{act}}(\Omega_k)$ and $G_{\text{fb}}(\Omega_k)$ are, respectively, the actuator and feedback dynamics. From (25), it follows that in those frequency bands where the process noise $V(k)$ dominates, one rather estimates minus the inverse of the feedback dynamics instead of the plant FRF. On the other hand, at those frequencies where the reference signal injects most power, the ETFE (25) will be close to the plant FRF.

If a known external reference signal is available, then the bias is avoided via the indirect method proposed in Wellstead (1981)

$$G(\Omega) = \frac{S_{yr}(\Omega)/S_{rr}(\Omega)}{S_{ur}(\Omega)/S_{rr}(\Omega)} = \frac{S_{yr}(\Omega)}{S_{ur}(\Omega)}. \quad (26)$$

The basic idea consists in modeling the feedback setup (see Fig. 2) from the known reference to the input and output simultaneously. This reduces the single-input, single-output closed loop problem to a single-input, two-output open loop problem. Since the process noise $v(t)$ is independent of the reference signal $r(t)$, the direct estimate of the single-input, two-output FRF is unbiased. Calculating the ratio of the two FRFs finally gives the indirect estimate (26). This procedure

Nonparametric Techniques in System Identification, Fig. 2 Plant operating in closed loop: $r(t)$ is the external reference signal, the known input $u(t)$ depends on the process noise $v(t)$, and $y(t)$ is the noisy output observation

can be applied to any of the direct methods of sections “Nonparametric Time-Domain Techniques” and “Nonparametric Frequency-Domain Techniques.” Proceeding in this way, unstable plants operating in a stabilizing feedback loop can also be handled.

If the excitation is *periodic*, then the process noise $v(t)$ is independent of the periodic part of the input $u(t)$, and the ETFE (14) converges to the true value as the number of periods P tends to infinity (Pintelon and Schoukens 2012, Section 2.5). Hence, in the periodic case, no external reference is needed.

Noisy Input, Noisy Output Observations

The key difficulty of estimating the FRF of a plant excited by a *nonperiodic signal* from noisy input, noisy output observations (see Fig. 3) is that the input autopower spectrum in (16) is biased. Indeed, due to the noise on the input, $S_{uu}(\Omega)$ is too large, resulting in too small direct FRF estimates. This is true for all direct FRF approaches in sections “Nonparametric Time-Domain Techniques” and “Nonparametric Frequency-Domain Techniques.” Applying the indirect method of section “Systems Operating in Feedback” removes the bias because the noise on the input is independent of the reference signal (e.g., see (26)). Proceeding in this way, the closed loop case (see Fig. 2) with noisy input, noisy output observations is also solved by the indirect method.

If the excitation is *periodic*, then the mean value of the input-output DFT spectra over the P consecutive periods converges to the their

true values as P tends to infinity (Pintelon and Schoukens 2012, Section 2.5). Hence, the ETFE (14) is still consistent, and no external reference is needed. The same conclusion is valid for systems operating in feedback.

Nonlinear Systems

The classes of nonlinear systems considered are those systems whose steady-state response to a periodic input is periodic with the same period as the input. It excludes phenomena such as chaos and subharmonics but allows for hard nonlinearities such as saturation, dead zones, and clipping.

The classes of excitations considered are stationary random signals with a specified power spectrum and probability density function. An important special case is the class of Gaussian excitation signals with a specified power spectrum. This class includes random phase multisines (a sum of harmonically related sinewaves with user-specified amplitudes and random phases) with the same Riemann equivalent power spectrum (Pintelon and Schoukens 2012, Section 4.2).

Consider a nonlinear (NL) period in, same period out (PISPO) system excited by a random excitation belonging to a particular class (see Fig. 4). The FRF (16), where the expected value is taken w.r.t. the random realization of the excitation, is the best (in mean square sense) linear approximation (BLA) of the nonlinear PISPO system, because the difference $y_s(t)$ between the actual output of the nonlinear system (DC value excluded) and the output predicted by the linear approximation is uncorrelated with the

Nonparametric Techniques in System Identification, Fig. 3 Errors-in-variables framework: $r(t)$ is the external reference signal; $n_g(t)$ is the generator noise; $m_u(t)$, $m_y(t)$

are the input and output measurement errors; $v(t)$ is the process noise; and $u(t)$, $y(t)$ are the noisy input, noisy output observations

Nonparametric Techniques in System Identification,

Fig. 4 Best linear approximation (BLA) of a nonlinear (NL) period in, same period out (PISPO) system, excited by a zero-mean random signal $u(t)$ with a given power spectrum and probability density function. $y(t)$ is the zero-mean part of the actual output of the nonlinear system. u_{DC} and y_{DC} are the DC levels of the actual input and output of the nonlinear system. The zero-mean output residual $y_s(t)$ is uncorrelated with – but not independent of – the input $u(t)$

input $u(t)$ (Enqvist and Ljung 2005). Although uncorrelated with the input, the output residual $y_s(t)$ still depends on $u(t)$. If the NL PISPO system operates in feedback (see Fig. 2), then the indirect method (26) is used for calculating the BLA, and the output residual $y_s(t)$ is uncorrelated with – but not independent of – the reference signal $r(t)$ (Fig. 2).

For the class of Gaussian excitation signals, it can be shown that the DFT spectrum $Y_S(k)$ of $y_s(t)$ has the following properties (Pintelon and Schoukens 2012, Section 3.4.4):

1. $Y_S(k)$ has zero-mean value: $\mathbb{E}\{Y_S(k)\} = 0$.
2. $Y_S(k)$ it is uncorrelated with – but not independent of – $U(k)$: $\mathbb{E}\{Y(k)\overline{U(k)}\} = 0$.
3. $Y_S(k)$ is asymptotically ($N \rightarrow \infty$) normally distributed.
4. $Y_S(k)$ is asymptotically ($N \rightarrow \infty$) uncorrelated over the frequency.

These second-order properties are exactly the same as those of a filtered white noise disturbance, except that the noise is independent of the input. It shows that it is impossible to distinguish the nonlinear distortions $y_s(t)$ from the disturbing noise $v(t)$ in FRF measurements using stationary random excitations (only second-order statistics are involved in (21)–(23)).

Using random phase multisines, it is possible to detect and quantify the nonlinear distortions

because $y_s(t)$ is then periodically related to the input $u(t)$ (property of the NL PISPO system). Indeed, analyzing the FRF over consecutive signal periods quantifies the noise variance $v(t)$ ($y_s(t)$ does not change over the periods), while analyzing the FRF over different random phase realizations of the input quantifies the sum of the noise variance and the variance of the nonlinear distortions ($y_s(t)$ depends on the random phase realization of the input). Subtracting both variances gives an estimate of the variance of the nonlinear distortions. While this variance quantifies exactly the variability of the nonparametric FRF estimate due to the nonlinear distortions, it can (significantly) underestimate the variability of a parametric plant model. The basic reason for this is that the true variance of the parametric plant model also depends on the nonzero higher (>2) order moments between the input $u(t)$ and the nonlinear distortions $y_s(t)$.

User Choices

There is no clear answer to the question which of the presented techniques is the best. It strongly depends on the intended use of the nonparametric estimates and the particular application handled. For example, the intended use can be:

1. A smooth representation of the FRF
2. Use of the nonparametric estimates as an intermediate step for parametric modeling of the plant

In the first case, one should opt for the minimum mean square error solution, while in the second case, it is crucial that the nonparametric estimates are unbiased, possibly at the price of an increased variance. Indeed, the parametric plant modeling step cannot eliminate the bias error in the nonparametric estimates while it suppresses the variance error.

The application-dependent answers to the following questions strongly influence the choice and the settings of the method used:

1. Is a large frequency resolution needed and/or is leakage the dominant error?

2. Is the noise or the leakage error dominant?
3. Is it necessary to detect and quantify the nonlinear behavior?

If the answer to the first question is yes, then one should opt for one of the advanced methods (section “Advanced Methods”) or use the spectral analysis estimates (section “Spectral Analysis Method”) with a small number M of subrecords. On the other hand, if the noise error is dominant, then M in (21)–(23) should be chosen as large as possible. To detect and quantify the nonlinear effects, one should use periodic signals (random phase multisines) combined with the ETFE (section “Empirical Transfer Function Estimation”).

Finally, comparing the different nonparametric techniques is also not straightforward because of their different

1. Frequency resolution
2. Quality of the estimated noise model
3. Correlation length over the frequency

The latter is set by the spectral width of the window used in the spectral analysis method and the local bandwidth in the advanced methods.

Guidelines

While the previous sections give well-established facts about the different nonparametric techniques, in this section, we provide some advices/guidelines based on our personal interpretation of these facts:

- Always store the reference signal together with the observed input-output signals. The knowledge of the reference signal allows one to solve nonparametrically the closed loop and errors-in-variables problems.
- Whenever possible use periodic excitation signals (random phase multisines): they allow one to estimate from one experiment the FRF, the noise level, and the level of the nonlinear distortions. As such the deviation of the true dynamic behavior from the ideal linear time-invariant framework is quantified.
- Select one of the advanced methods if frequency resolution is of prime interest.
- If the goal of the identification experiment is to minimize the prediction error, then the Gaussian process regression method is a very promising approach.
- For lowly damped systems and a limited frequency resolution, the local rational method is a good candidate solution.
- Use a minimum mean square solution for a smooth representation of the FRF.
- Choose unbiased nonparametric estimates for use in parametric plant modeling (estimation, validation, and model selection).
- When comparing nonparametric techniques, always take into account all aspects of the estimates: the bias and variance of the FRF and noise model, the frequency resolution, and the correlation length over the frequency.

Summary and Future Directions

Nonparametric techniques are very useful because they simplify the parametric plant modeling in the initial selection of the model complexity and in the detection of unmodeled dynamics. The classical correlation and spectral analysis methods developed in the 1950s and refined till the 1980s are still widely used. Recently, advanced time- and frequency-domain methods have been developed which all try to minimize the sensitivity (bias and variance) of the nonparametric estimates to disturbing noise, nonlinear distortion, and transient (leakage) errors.

The renewed research interest in nonparametric techniques should be continued to handle the following challenging problems: short data sets, missing data, detection and quantification of time-variant behavior, modeling of time-variant dynamics, and modeling of nonlinear dynamics.

Nonparametric Techniques in System Identification: The Time-Varying and Missing Data Cases

Rik Pintelon and J. Lataire
Department ELEC, Vrije Universiteit Brussel,
Brussels, Belgium

Abstract

This entry is an extension of the nonparametric techniques presented in “► [Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens, to time- and

parameter-varying systems and missing data problems. To increase its readability, we first briefly recall in the introduction some definitions given in “► [Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens, and clarify the leakage contribution to nonparametric frequency response function (FRF) estimation. Given its importance in the nonparametric estimation of time- and parameter-varying dynamics, the entry starts by describing the newest developments in advanced techniques for estimating FRFs. Next, the time-varying, parameter-varying, and missing data cases are handled.

As a main result the reader will learn about (i) the detection and quantification of time-varying effects and nonlinear distortions in FRF estimates, (ii) the estimation of time- and parameter-varying FRFs, and (iii) the estimation of (time-varying) FRFs in the presence of missing data. All results are valid for discrete- and continuous-time systems operating in open or closed loop.

Keywords

Best linear time-invariant approximation · Frequency response function · Local rational methods · Parameter-varying systems · Time-varying frequency response function · Missing data

Introduction

Nonparametric estimation typically starts from sampled input-output signals $u(nT_s)$ and $y(nT_s)$, $n=0, 1, \dots, N-1$. In a frequency domain approach, these samples are transformed into the frequency domain via the discrete Fourier transform (DFT)

$$X(k) = \text{DFT}\{x(t)\} = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} x(nT_s) z_k^{-n} \quad (1)$$

with $z_k = e^{j2\pi k/N}$, T_s the sampling period, $x=u$ or y , and $X = U$ or Y . A major issue in FRF and noise power spectra estimation is the leakage

error in the DFT spectrum (1) (see Brillinger 1981). This error is due to the finite duration NT_s of the experiment and increases the mean square error of the estimates. However, it is zero for time-limited signals and periodic signals that are sampled coherently (Pintelon and Schoukens 2012, Sections 2.2.3 and 2.2.4).

For arbitrary excitations $u(t)$, the relationship between the true input $U(k) = \text{DFT}\{u(nT_s)\}$ and true output $Y_0(k) = \text{DFT}\{y_0(nT_s)\}$ discrete Fourier transform spectra (1) of a linear dynamic system is given by

$$Y_0(k) = G(\Omega_k) U(k) + T_G(\Omega_k) \quad (2)$$

where $\Omega_k = j\omega_k$ or $\exp(-j\omega_k T_s)$ for, respectively, continuous- and discrete-time systems; $\omega_k = 2\pi k/(NT_s)$; $G(\Omega_k)$ the plant frequency response function; and $T_G(\Omega)$ a rational function of Ω that decreases to zero as $O(N^{-1/2})$ for N increases to infinity (Pintelon and Schoukens 2012, Section 6.3.2). The numerator coefficients of $T_G(\Omega)$ depend on the difference between the initial and final conditions of the experiment, and $T_G(\Omega)$ has the same denominator as the plant transfer function $G(\Omega)$. Therefore, the time domain response of $T_G(\Omega)$ is decaying exponentially to zero as a transient error. Since $T_G(\Omega_k)$ is zero when the initial and final conditions are equal (e.g., for time-limited input-output signals or coherently sampled steady-state responses to periodic excitations), it is called the leakage error here.

First, the newest developments in advanced nonparametric frequency domain techniques are described (section “[Advanced Nonparametric Frequency Domain Techniques](#)”). The reason for this is that the nonparametric estimation of time-varying dynamics can be reformulated as a multivariate FRF estimation problem (section “[Detection and Quantification of Time-Varying Effects](#)”). Moreover, some of the nonparametric methods for estimating parameter-varying dynamics also rely on advanced frequency domain methods (section “[Parameter-Varying Systems](#)”). Next, section “[Missing Data](#)” handles the estimation of (time-varying) frequency response functions in the presence of

missing data. Further, some additional practical guidelines are given in section “[Guidelines](#)”. Finally, section “[Summary and Future Directions](#)” summarizes the main results and indicates some future research directions.

Advanced Nonparametric Frequency Domain Techniques

Leakage is a major issue in FRF estimation of lowly damped systems. Using the smoothness of the FRF and the leakage error, advanced methods have been developed that suppress better the impact of leakage on the estimates than the standard spectral analysis methods (see “[Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens). In this section we briefly discuss the newest developments.

A *first class* of methods approximates the FRF and the leakage error in (2) in a local frequency band $[k - n, k + n]$ by a polynomial (see “[Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens). This procedure is then repeated for all frequencies k of interest. The local polynomial approximation works well so long as the frequency resolution of the measurement is large enough (more than seven frequencies within the 3 dB bandwidth of the resonances).

To handle lowly damped systems measured with a low frequency resolution (less than seven frequencies within the 3 dB bandwidth of the resonances), a *second class* of methods has been developed that approximates the FRF and the leakage error locally by a rational function. In McKelvey and Guérin (2012), the local rational approximation problem is transformed into a linear least squares problem via a common denominator parametrization of the FRF and the leakage error ($G = B/A$ and $T_G = I/A$). Although the resulting estimator is biased, it works well for lowly damped systems and sufficiently high signal-to-noise ratios (typically ≥ 40 dB). In Voorhoeve et al. (2018), this method is extended to multivariate frequency response functions that are locally approximated by a

left matrix fraction description. To avoid the bias of the linear least squares approach, the local parameters are obtained by minimizing $\|Y - GU - T_G\|_2^2$ over each local frequency band. This requires a nonlinear optimization, which is circumvented in Peumans et al. (2018) via a weighted total least squares estimator.

Extensions to the Time-Varying and Missing Data Cases

In “[Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens, it is assumed that the plant dynamics are time-invariant. However, in quite some (bio-) engineering applications, the dynamics are time- or parameter-varying, for example, thermal drift in power electronics, pit corrosion of metals, muscle fatigue in biomedical experiments, myocardial electrical impedance spectroscopy. The time variation can also be the consequence of a linearization of nonlinear dynamics around a varying set point or a periodic steady-state solution. Section “[Detection and Quantification of Time-Varying Effects](#)” discusses the detection, quantification, and nonparametric modeling of the time-varying effects in FRF estimates, while parameter-varying systems are handled in section “[Parameter-Varying Systems](#)”.

Due to sensor malfunction, for example, saturation, clipping, and outliers, and/or data loss during wireless transmission, FRF estimates are subject to missing data. How to handle missing data in FRF estimation is explained in section “[Missing Data](#)”.

Detection and Quantification of Time-Varying Effects

Under some smoothness assumption on the time variation, the time-varying dynamics of a linear time-varying system are uniquely characterized by the time-varying frequency response function (TV-FRF) $G(j\omega, t)$ introduced in Zadeh (1950a). It is related to the time-varying impulse response $g(t, \tau)$ [$y(t) = \int_0^t g(t, \tau)u(\tau)d\tau$] via the Fourier transform

$$G(j\omega, t) = \mathcal{F}_\tau \{g(t, t - \tau)\} \\ = \int_0^\infty g(t, t - \tau) e^{-j\omega\tau} d\tau \quad (3)$$

where t is the response time and τ the time at which the Dirac impulse is applied to the system. The time-varying FRF (3) has the following properties:

1. The steady-state response $y(t)$ to a sinewave input $u(t) = A \sin(\omega t)$ is given by

$$y(t) = A |G(j\omega, t)| \sin(\omega t + \angle G(j\omega, t)) \quad (4)$$

2. The transient response $y(t)$ to an arbitrary input $u(t)$ is calculated as

$$y(t) = \mathcal{L}^{-1} \{G(s, t)U(s)\} \quad (5)$$

where $U(s)$ is the Laplace transform of $u(t)$ and with $\mathcal{L}^{-1} \{ \}$ the inverse Laplace transform

(see Zadeh 1950a). Note that these properties are natural extensions of those of an FRF.

Assuming that $G(j\omega, t)$ is a smooth function of t , it can be expanded in series as

$$G(j\omega, t) = \sum_{m=0}^{\infty} G_m(j\omega) f_m(t) \\ \approx \sum_{m=0}^{N_b} G_m(j\omega) f_m(t) \quad \text{for } t \in [0, T] \quad (6a)$$

with $f_m(t)$, $m = 0, 1, \dots$ a complete set of basis functions over $[0, T]$ satisfying

$$f_0(t) = 1 \quad \text{and} \quad \frac{1}{T} \int_0^T f_m(t) dt = 0 \quad \text{for } m \neq 0 \quad (6b)$$

for example, a polynomial basis (arbitrary time variation) or sines and cosines (periodic time variation).

Combining (5) with (6) results in the block diagram shown in Fig. 1. The output gains of this block diagram can be shifted to the input resulting in the indirect model in Fig. 2. There exists an analytic relationship between the FRFs $G_m(j\omega)$ in the direct model and the FRFs $H_m(j\omega)$ in the indirect model (see Pintelon et al. 2015, for polynomial basis functions). For example, for the choice $f_{\pm m}(t) = e^{\pm j m \omega_{\text{sys}} t}$, with ω_{sys} the angular frequency of the periodic time variation, the FRFs

N

Nonparametric Techniques in System Identification: The Time-Varying and Missing Data Cases,
Fig. 1 Direct model (right block diagram) of the time-varying frequency response function $G(j\omega, t)$

Nonparametric Techniques in System Identification: The Time-Varying and Missing Data Cases,
Fig. 2 Indirect model (right block diagram) of the time-varying frequency response function $G(j\omega, t)$

are related as

$$G_{\pm m}(j\omega) = H_{\pm m}(j(\omega \pm m\omega_{\text{sys}})) \quad (7)$$

for $m = 0, 1, \dots, N_b$.

Since the inputs $u_m(t)$ of the linear time-invariant blocks $H_m(j\omega)$ in Fig. 2 are linearly independent (the gains $f_m(t)$ form a basis), the indirect model can be viewed as a multiple-input, single-output linear time-invariant system. Hence, the FRFs $H_m(j\omega)$ can be estimated from input-output data using the techniques of section “[Advanced Nonparametric Frequency Domain Techniques](#)” and, next, transformed into $G_m(j\omega)$ (see (7) for complex exponential basis functions and Pintelon et al. (2015) for polynomial basis functions).

The direct model in Fig. 1 can be redrawn as in Fig. 3, where $y_{\text{TV}}(t)$ quantifies the impact of the time-varying branches in the direct model and where $G_0(j\omega)$ can be interpreted as the best linear time-invariant approximation (Lataire et al. 2012). Since $Y_{\text{TV}}(k) = \text{DFT}\{y_{\text{TV}}(t)\}$ has the following properties

1. $Y_{\text{TV}}(k)$ has zero mean value: $\mathbb{E}\{Y_{\text{TV}}(k)\} = 0$.
2. $Y_{\text{TV}}(k)$ is uncorrelated with – but not independent of – $U(k)$: $\mathbb{E}\{Y_{\text{TV}}(k)U(k)\} = 0$.
3. $Y_{\text{TV}}(k)$ is not asymptotically ($N \rightarrow \infty$) normally distributed.

Nonparametric Techniques in System Identification: The Time-Varying and Missing Data Cases, Fig. 3 Best linear time-invariant approximation $G_0(j\omega)$ of a linear time-varying system. The output residual $y_{\text{TV}}(t)$ represents the time-varying effects, and $Y_{\text{TV}}(k) = \text{DFT}\{y_{\text{TV}}(t)\}$ is uncorrelated with – but not independent of – $U(k) = \text{DFT}\{u(t)\}$

4. $Y_{\text{TV}}(k)$ is not asymptotically ($N \rightarrow \infty$) uncorrelated over the frequency.

(see Lataire et al. 2012), it acts as non-Gaussian frequency correlated noise on FRF estimates.

The concept of the best linear time-invariant approximation can be generalized to nonlinear time-varying systems (Ljung 2001). Assuming that the time-invariant branch in the direct model of Fig. 1 is a nonlinear period-in, same period-out system (see “[Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens), the $G_0(j\omega)$ block in Fig. 3 is replaced by the best linear approximation of the nonlinear time-invariant block plus an output residual $y_s(t)$ (see “[Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens; and Enqvist and Ljung 2005). This results in a best linear time-invariant approximation (BLTIA) of the nonlinear time-varying system with an output residual that consists of two contributions: a nonlinear distortion $y_s(t)$ and a time-varying effect $y_{\text{TV}}(t)$ (see Fig. 4). The DFT spectra of these residuals are uncorrelated

$$\mathbb{E}\{Y_S(k)\overline{Y_{\text{TV}}(k)}\} = 0$$

and using specially designed periodic excitation signals, it is possible to detect and quantify their presence in noisy FRF estimates (Pintelon et al. 2013).

If a known reference signal is available then, following the same lines of “[Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens, nonlinear time-varying systems operating in closed loop can be handled (Pintelon et al. 2013).

Parameter-Varying Systems

In quite some applications, the time variation is induced by one or more known physical quantities called the scheduling parameters $p(t)$, for example, the speed and height in airplane dynamics or the varying set point in the local linearization of a nonlinear dynamical system. The connection between parameter- and time-varying systems is that each particular trajectory of the scheduling parameter $p(t)$

Nonparametric Techniques in System Identification: The Time-Varying and Missing Data Cases, Fig. 4

Best linear time-invariant approximation (BLTIA) of a nonlinear time-varying (NLTV) system excited by a zero mean random excitation $u(t)$ with a given power spectral density and probability density function. $y(t)$ is the zero mean part of the actual output of the nonlinear time-varying system. u_{DC} and y_{DC} are the DC levels of the actual input and output of the system. Assuming that the output can be split into a nonlinear time-invariant and a linear time-varying contribution, the difference between the actual output $y(t)$ and the output $y_{BLTIA}(t)$ of the BLTIA can be split into a stochastic nonlinear distortion $y_S(t)$ and a time-varying effect $y_{TV}(t)$. $Y_S(k) = \text{DFT}\{y_S(t)\}$ and $Y_{TV}(k) = \text{DFT}\{y_{TV}(t)\}$ are mutually uncorrelated and uncorrelated with $-$ but not independent of $-U(k) = \text{DFT}\{u(t)\}$

defines a time-varying system. Therefore, the time-varying frequency response function (3) can be generalized to a parameter-varying frequency response function $G_{p(t)}(j\omega, t)$. Linear parameter-varying models are more powerful than linear time-varying models because they are also valid for other trajectories of $p(t)$. As such, linear parameter-varying models can be used for prediction and control purposes (Tóth 2010). They are also a first step toward the modeling and control of nonlinear dynamics (Bamieh and Giarré 2002).

The parameter-varying dynamics can be measured via a local or a global experiment:

- Local experiment: Several experiments are performed for different fixed values of $p(t)$.
- Global experiment: One experiment is performed with a varying $p(t)$.

While the global experiments can handle dynamic dependencies on $p(t)$, the local

experiments are suitable for modeling static dependencies on $p(t)$ or slow (w.r.t. the system bandwidth) parameter variations only.

Local experiments are used in van der Maas et al. (2017) to estimate nonparametrically $G_{p(t)}(j\omega, t)$ via a local polynomial approximation over the frequency and the scheduling parameter(s).

Using (Gaussian) kernel functions (Pillonetto et al. 2011) and one global experiment, parameter-varying state space and Box-Jenkins models are estimated nonparametrically in Rizvi et al. (2018) and Darwish et al. (2018).

Missing Data

Assuming that M_y consecutive output samples are missing starting at position K_y , relationship (2) is modified as

$$Y_0^m(k) = G(\Omega_k)U(k) + T_G(\Omega_k) - \frac{1}{\sqrt{N}} z_k^{-K_y} \sum_{n=K_y}^{K_y+M_y-1} y_0(nT_s) z_k^{-n} \quad (8)$$

with $Y_0^m(k)$ the output DFT spectrum (1) where the missing samples are set to zero and with $y_0(nT_s)$, $n = K_y, \dots, K_y + M_y - 1$, the missing output samples. Approximating the FRF $G(\Omega_k)$ for each value of k in a local frequency band around k by a polynomial (see “► Nonparametric Techniques in System Identification”, by Rik Pintelon and Johan Schoukens) transforms (8) into a sparse overdetermined set of equations that can be solved time and memory efficiently using QR-decompositions (Ugryumova et al. 2015).

Note that (8) can easily be extended to the case where (blocks of) samples are missing at non-consecutive time instants. As such, any missing data pattern (e.g., bursts, random, clipping) can be handled so long as missing samples do not occur at the borders of the record. The reason for the latter is that data missing at the borders cannot be distinguished from $T_G(\Omega_k)$ in (8).

If a known reference signal is available then, following the same lines of “► Nonparametric Techniques in System Identification”, by Rik Pintelon and Johan Schoukens, missing input data

and systems operating in closed loop can be handled (Ugryumova et al. 2015).

Since the estimation of the time-varying FRF can be reformulated as the estimation of a multiple-input, single-output FRF, the missing data algorithm developed in Ugryumova et al. (2015) for time-invariant systems is also applicable to the time-varying case (Pintelon et al. 2017).

Guidelines

In addition to the guidelines of “► [Nonparametric Techniques in System Identification](#)”, by Rik Pintelon and Johan Schoukens:

- If lowly damped systems are measured with a limited frequency resolution (less than seven frequencies within the 3 db bandwidth of the resonance), then the local rational methods of section “[Advanced Nonparametric Frequency Domain Techniques](#)” for estimating the FRF are preferred over the local polynomial methods.
- Use periodic excitation signals (random phase multisines), whenever possible: they allow one to estimate from one experiment the FRF, the noise level, and the level of the nonlinear distortions and time-varying effects. Proceeding in this way, the deviation of the true dynamic behavior from the linear time-invariant framework is detected and quantified.
- If data is missing, then the best option is to fix the hardware problem and to redo the experiment(s). If this is not possible because of time and/or cost or because it concerns historical data sets, then the missing data techniques of section “[Missing Data](#)” are very helpful.

Summary and Future Directions

Leakage suppression in frequency response function estimates of lowly damped systems remains a challenging problem. Therefore, there

is a continuing interest to improve the existing advanced methods. Currently, the problem of handling a large number of inputs and outputs is addressed (Peumans et al. 2019).

Using a special class of periodic excitation signals, the recently developed nonparametric techniques allow one to detect and quantify the disturbing noise, the nonlinear distortion, and the time-varying effects in frequency response function estimates. As such, via a simple experiment, the (in)validity of the linear time-invariant framework can easily be established before the parametric modeling step. It answers the following important questions: “Is a linear time-invariant model accurate enough for my application?”, “Can I neglect or do I need to model the nonlinear behavior?”, and “Is time variation of the dynamics an issue?”. Note that all of this is possible in the presence of missing data.

Although started in the early 1950s by the work of Zadeh (1950a, b), a renewed interest in modeling time- and parameter-varying dynamics is observed in the literature. One of the reasons for this is that time-varying-models are a first step toward parameter-varying modeling, while the latter is on its turn a first step toward nonlinear modeling.

The ongoing research interest in nonparametric techniques should be continued to handle the following challenging problems: short data sets and fast time and parameter variations. Although some interesting initial results are available, more effort is needed on nonparametric modeling of parameter-varying (see section “[Parameter-Varying Systems](#)”) and nonlinear (see Birpoutsoukis et al. 2017) dynamical systems.

Recommended Reading

The theory of time-varying systems is well covered by the early work of Zadeh (1950a,b) and the book of Rugh (1996). Some basics about parameter-varying systems can be found in the book of Tóth (2010). In addition, the recommended reading list includes the most recent developments described in sections “Advanced Nonparametric Frequency Domain Techniques”, “Extensions to the Time-Varying and Missing Data Cases”, and “Summary and Future Directions”.

Non-raster Methods in Scanning Probe Microscopy

Sean B. Andersson
Mechanical Engineering and Division of
Systems Engineering, Boston University,
Boston, MA, USA

Abstract

Scanning probe microscopy (SPM) refers to a family of technologies for probing systems with nanometer-scale features in which a

probe interacts with a sample. Traditionally, images of a signal of interest are built pixel-by-pixel by rastering the probe across the sample. While simple, this method is at least partially responsible for the slow imaging times which are inherent to SPM imaging. Non-raster methods seek to improve image acquisition time by modifying this scanning process to one that is more efficient. This efficiency can be with respect to the probe trajectories, moving to patterns that are easier for scanners to follow, or it can be with respect to scanning area, increasing speed by reducing the amount of scanning to be done.

Keywords

High-speed SPM · Non-raster scanning · Feature-based imaging

Introduction

Scanning probe microscopy (SPM) refers to a broad class of technologies aimed at studying samples with nanometer-scale features. The essential idea is to measure some physical property of the sample, such as topography, material stiffness, conductance, temperature, and many others, through the local interaction between the sample and a probe. An image of this property is formed by rastering the probe across the sample, building the result pixel-by-pixel. There are a variety of names under the SPM umbrella depending on the type of interaction and physical property being measured, including scanning tunneling microscopy (STM), which measures the tunneling current between a sharp tip and the sample surface; atomic force microscopy (AFM) (also known as scanning force microscopy), which measures the interaction force between a sharp tip on the end of a cantilever and the sample; near-field scanning optical microscopy (NSOM), which uses the near-field of a light source to probe the sample surface; and many others.

The probe is typically actuated relative to the sample using a piezoelectric scanning stage and

the signal of interest (such as the tunneling current or the cantilever deflection) is held constant by using a feedback loop to actuate the vertical position of the probe relative to the surface. Due to a combination of the mechanical limitations of the scanning process (such as the bandwidths of the actuators and induced vibrations of the stages) and the fact that images are built pixel by pixel, the imaging process can be very slow. For example, for many AFMs the imaging time is on the order of seconds to minutes. While this is not a major limitation for measuring static signals, it is a severe drawback when studying dynamics in systems with nanometer-scale features or in applications where throughput is a significant concern.

Improving the imaging time of SPM can have a major impact on a broad array of applications, from understanding dynamics in biomolecular systems to high-throughput testing of novel engineered materials. As a result, there is a significant body of literature on overcoming this challenge. Approaches can be broadly categorized into three bins: faster hardware, faster controllers, and alternative (non-raster) scanning. As SPM devices are mechanical microscopes, faster hardware means reducing the physical time constants of different elements in the systems, from the piezoelectric scanners (Yong and Leang 2016) to the probe used to interact with the sample (Walters et al. 1998). The second category, faster controllers, seeks to do more with the existing hardware, applying approaches like adaptive proportional-integral-derivative (Ando 2012), robust control (Helfrich et al. 2009), and feedforward control (Clayton et al. 2009). Combining techniques from these two categories has led to instruments that are orders of magnitude faster than older generations, opening up new avenues of research (Ando et al. 2013; Heron et al. 2014; Yoshioka et al. 2018).

The third category of methods for high-speed AFM, namely non-raster scanning, is the focus of this encyclopedia entry. Non-raster scanning methods, which build an image using alternatives to the simple raster scan, can be loosely organized into three groups: full scans using patterns with reduced frequency content when compared to

the raster pattern, sub-sampling combined with image reconstruction, and local, feature-based methods. The first of these seeks to improve the imaging rate by moving the probe faster than in the raster-scan pattern, while the second two both aim to reduce the imaging time by reducing the number of pixels that are measured. Non-raster methods are complementary to the hardware and control schemes and thus can be combined with either or both for the most impact.

The goal of this entry is to introduce the interested reader to the general ideas in non-raster scanning and provide at least one view on the direction the field is moving. While this is not a survey paper, a few select references are provided throughout to point the reader in hopefully fruitful directions into the literature.

Scanning Patterns with Reduced Frequency Content

In the basic raster scan pattern, shown in Fig. 1a, the probe is scanned using a triangle wave in one direction (the *fast scan* direction) and a ramp in the other (the *slow scan* direction). Note that, as shown in the figure, the pattern makes two passes over a single row of pixels, one in each direction. Due to details of the probe-sample interaction, the measurements differ somewhat in the two directions and thus each scan yields *two* images: a trace scan and a retrace scan. Given a specific frame rate, then, the probe actually moves twice as fast as might be expected.

The primary challenge of the raster-scan pattern is the fact that accurate tracking of the triangle wave requires high bandwidth nanopositioners. For example, to scan an area of $5\ \mu\text{m} \times 5\ \mu\text{m}$ with a resolution of 5 nm in a total time of 1 s, the fast axis must track a 1 kHz triangle wave. To ensure that at least the first five harmonics are covered, the actuator bandwidth must be at least 10 kHz. At lower bandwidths, the output trajectory lags the input and rounds off the corners. This is illustrated in Fig. 1d which shows the reference triangle wave (blue) and the output using an actuator with a (closed-loop) bandwidth sufficient to capture the first 10 harmonics (black)

and with a bandwidth only sufficient for the first five (red). This finite bandwidth eventually limits the frequency of triangle wave which can be reasonably tracked and thus the frame rate that can be achieved.

Clearly one approach to overcoming this limitation is to increase the bandwidth of the scanning stage; this is the goal of the first two categories noted in section “[Introduction](#)” through either hardware or control design. An alternative is to replace the raster scan pattern with one that has lower frequency content than the triangle wave and which thereby allows faster scan patterns without changes in the hardware or controller.

While there are a variety of curves that can be used, there are two primary ones that have been applied: spiral scans and Lissajous patterns. Under a spiral scan, the probe is driven along an Archimedean spiral, shown in Fig. 1b and defined by

$$x(t) = r(t) \cos(\omega t),$$

$$y(t) = r(t) \sin(\omega t),$$

$$r = \frac{P}{2\pi} \omega t,$$

where P is the pitch of the spiral (defining the resolution of the scan) and ω is the frequency of rotation. In particular, there is a single frequency of growing amplitude in each axis, as illustrated in Fig. 1e and as a result the scanning stage can be driven at a high frequency without exciting mechanical resonances of the scanner.

By construction, spiral scan patterns cover a circular imaging area. An alternative family of scan patterns are those defined by Lissajous curves where the two axes are driven according to

$$x(t) = \frac{A}{2} \sin(2\pi f_x t), \quad y(t) = \frac{B}{2} \sin(2\pi f_y t),$$

where A determines the range of the scan while the frequencies f_x and f_y define both the shape and total imaging time of the scan. While these trajectories are quite easy to implement, they do yield a variable resolution across the image.

Non-raster Methods in Scanning Probe Microscopy, Fig. 1 Different scan trajectories for full-frame scanning. (a) Standard raster scan and (d) fast axis tracking. Slower actuators (or faster scans) clip more of the high-frequency content of the triangle wave, leading to poor tracking. (b)

Spiral scans steer the probe along an Archimedean spiral using (e) a single frequency with time-varying amplitude. (c) Lissajous scans scan the image area by (f) driving the two actuators using two different frequencies

Both of these patterns have been implemented by multiple groups and combined with both novel actuators and advanced controllers to yield frame rates significantly above 1 Hz (Tuma et al. 2012; Rana et al. 2014; Bazaei et al. 2017). Because the patterns sample all the pixels, the images are completely equivalent to those created by a raster scan (with the exception that a spiral scan image area is circular rather than rectangular).

Sub-sampling the Image

The scanning patterns discussed in section “[Scanning Patterns with Reduced Frequency Content](#)” only address limitations due to the bandwidth of the scanning actuators. As the speed of the probe increases, features are encountered more rapidly and thus the bandwidth of the vertical

axis must often also be increased to keep pace with the faster scanning (Teo et al. 2016). The second group of non-raster methods seeks to improve imaging rate by sampling less rather than scanning faster. That is, the entire image is sub-sampled and the final result generated from this sub-sampled data using image reconstruction algorithms.

A variety of sampling patterns can be applied, including simple row-subsampling (Fig. 2a), wide spirals (Fig. 2b), or randomly selected, short horizontal paths known as μ -path patterns (Fig. 2c) (Braker et al. 2018). In some patterns, the probe is repeatedly engaged to the sample, scanned, and then disengaged to move to a new measurement location. This can help with increasing the randomness in the sampling pattern but also slows the overall imaging rate as the engagement process can take a significant

Non-raster Methods in Scanning Probe Microscopy, Fig. 2 Example sub-sampling patterns. Blue, solid lines indicate where measurements are acquired while red, dotted lines indicate where the probe is simply moved to the next sampling position. (a) Row sub-sampling scans randomly selected rows. (b) Spiral sub-sampling steers

the probe along a wide spiral. (c) μ -path sub-sampling moves the probe along short, randomly selected horizontal paths. (d) Experimental result using a μ -path scan of a linear grating based on 15% sampling. Image reproduced with permission from (Braker et al. 2018). Tick marks are 10 μm and the colorbar units are nm

amount of time. As noted below, however, the randomness has a positive impact on the quality of the final image and thus can be worth the time penalty.

Once the data has been collected, a complete image must be generated from the sub-sampled data. Once again there are a variety of methods for achieving this with the two main groups of algorithms being inpainting and sparse reconstruction (Chen et al. 2012; Luo and Andersson 2015). Inpainting schemes seek to fill in missing data using information from nearby pixels. It is

important to note that the methods do not simply average neighboring data (as would be done in interpolation) but rather attempt to continue image features into the unknown regions. The methods work well for capturing low frequency content but can miss high frequency details.

Sparse reconstruction leverages the fact that most natural images are approximately sparse when expressed in an appropriate basis (such as a discrete cosine or wavelet representation), meaning that most of the image information is captured by a small number of coefficients, often

as low as 1%. These algorithms produce the final image through an optimization problem of the form

$$\min \|\eta\|_1 \text{ subject to } \|y - \Phi \Psi \eta\|_2 \leq \epsilon$$

where Φ is the measurement matrix describing which pixels of the image are sampled, Ψ is the selected basis, $\eta = \Psi^{-1}x$ is the representation of x in that basis, y is the vector of measurements, $\|\cdot\|_{1,2}$ is the l_1 or l_2 norm, and ϵ is a real number allowing for some noise in the measurements. Randomness in the measurements leads to a good value of a property known as mutual coherence and from there a better bound on the error of the reconstruction. Sparse reconstruction is a very rich field with many algorithms and a deep literature (see, e.g. (Zhang et al. 2015b)). These algorithms can produce high-quality reconstructions provided the assumption of (approximate) sparsity is met.

Feature-Tracking

Both of the previous two groups of sub-sampling methods aim to produce entire images from sub-sampled data. In many cases, however, such as when interested in dynamics occurring on a biopolymer or the growth of a crystal boundary, the area of interest is a small fraction of the overall image. This final group of approaches is similar to sub-sampling in that the improvement in imaging rate is due to a reduction of sampling rather than an increase in the speed of the probe relative to the sample. Unlike the sub-sampling approaches, however, this group aims to focus the measurements in the region of interest, using feedback to track a sample feature.

The basic idea is to steer the probe along a local dither pattern, such as a sinusoid or circle, detect in real time the presence of the feature in that local scan, and update the pattern to track the spatial evolution of the feature. As an example, consider imaging a thin but long sample such as a strand of DNA or a length of actin. As illustrated in Fig. 3a, the location of the feature of interest can be determined from the data and the future

evolution of that feature can be predicted. The probe is then moved along that predicted path and feedback used to correct any prediction error. The method has been used to image DNA (Hartman and Andersson 2018) and to quickly build contour maps of cells (Zhang et al. 2015a). Because it naturally eliminates drift in the microscope over time, the method will likely be particularly beneficial to examine samples over long periods of time. These algorithms can yield over an order-of-magnitude improvement in imaging rate for samples to which they apply, without any need to increase probe speed or improve the system hardware.

Summary and Future Directions

Improvements in the hardware and control algorithms have been making their way into industrial instruments, leading to the current generation of high-speed instruments, particularly in atomic force microscopy, with frame rates from 1 to 10 frames/second. Non-raster methods, on the other hand, remain primarily in the labs of individual researchers and have not yet made it into common usage. Despite this, they offer significant potential for drastic improvement in imaging rate and can be applied even to the latest instruments to further improve their imaging speed. Realizing this potential, however, relies on overcoming a variety of challenges. For both reduced frequency content and feature-based tracking patterns, vertical features arrive more rapidly than in standard raster scanning and thus the bottleneck shifts to the vertical bandwidth. These techniques will therefore have the most impact when combined with next-generation vertical positioners and control algorithms. Sub-sampling schemes by design do not sample the entire imaging area, inferring information from the acquired data. Open questions remain about how to ensure the information at a given resolution level has been completely acquired. Adaptive schemes aimed at either refining measurements over time or adjusting measurements in response to dynamic changes

Non-raster Methods in Scanning Probe Microscopy,

Fig. 3 Illustrating feature-tracking based imaging. (a) The path of the probe (blue, circular curve) is determined in real time using feedback from the measurements to follow the spatial evolution of the sample (black curve). (b) The location of the feature is determined from a signal available in real time such as the amplitude of the cantilever motion in tapping mode AFM. As the probe

moves from surface to sample, there is a momentary spike in the amplitude signal before the controller can regulate its value back to the setpoint. Looking for values that exceed a threshold (red line) indicate the location of the sample edge (simulated data). in the sample are likely to prove particularly beneficial.

Numerical Methods for Continuous-Time Stochastic Control Problems

George Yin

Department of Mathematics, Wayne State University, Detroit, MI, USA

Abstract

This expository article provides a brief review of numerical methods for stochastic control in continuous time. It concentrates on the methods of Markov chain approximation for controlled diffusions. Leaving most of the technical details out with the broad general audience in mind, it aims to serve as an introductory reference or a user's guide for researchers, practitioners, and students who wish to know something about numerical methods for stochastic control.

Keywords

Markov chain approximation · Numerical methods · Stochastic control

Introduction

This expository article provides a brief review of numerical methods for stochastic control in continuous time. Leaving most of the technical details out with the broad general audience in mind, it aims to serve as an introductory reference for researchers, practitioners, and students, who wish to know something about numerical methods for stochastic controls.

The study of stochastic control has witnessed tremendous progress in the last few decades; see,

for example, Fleming and Rishel (1975), Fleming and Soner (1992), Kushner (1977), and Yong and Zhou (1999) among others, for fundamentals of stochastic controls as well as historical remarks. Much of the development has been accompanied by the needs and progress in science, engineering, as well as finance. Typically, the problems are highly nonlinear, so a closed-form solution is very difficult to obtain. As a result, designing feasible numerical algorithms becomes vitally important. Among the many approximation methods, the Markov chain approximation methods have shown most promising features. Primarily for treating diffusions, the Markov chain approximation method was initiated in the 1970s (Kushner 1977) and substantially developed further in Kushner (1990b) and Kushner and Dupuis (1992). Nowadays, such method are used for more complex jump diffusions, or systems with random switchings. There were also efforts to incorporate the methods into an expert system so that the methods can be placed into an easily usable tool box (Chancelier et al. 1986, 1987). In addition to the existing applications in a wide variety of engineering problems, recently applications include such areas as insurance, quantile hedging for guaranteed minimum death benefits, dividend payment and investment strategies with capital injection, singular control, risk management, portfolio selection with bounded constraints, and production planning and manufacturing problems; see Jin et al. (2011, 2012, 2013), Sethi and Zhang (1994), and Yin et al. (2009) and references therein.

Let us begin with the controlled diffusion problem. We wish to minimize the cost function defined by

$$J(x, u(\cdot)) = E_x \left[\int_0^\tau R(X(t), u(t)) dt + B(X(\tau)) \right], \quad (1)$$

with the $\mathbb{R}^r$ -valued process $X(t)$ defined by the solution of the stochastic differential equation

$$dX(t) = b(X(t), u(t))dt + \sigma(X(t))dW,$$

$$X(0) = x \quad (2)$$

where $x \in \mathbb{R}^r$, $u(\cdot)$ is a U -valued, measurable process with $U \subset \mathbb{R}^d$ being a compact control set, $W(\cdot)$ is an r -dimensional standard Brownian motion, and τ is the first exit time of the diffusion from a bounded domain D , that is, $\tau = \min\{t : X(t) \notin D^0\}$ with D^0 denoting the interior of D , $b(\cdot, \cdot) : \mathbb{R}^r \times \mathbb{R}^d \mapsto \mathbb{R}^r$, $\sigma(\cdot) : \mathbb{R}^r \mapsto \mathbb{R}^r \times \mathbb{R}^r$, and $R(\cdot, \cdot) : \mathbb{R}^r \times \mathbb{R}^d \mapsto \mathbb{R}$ and $B(\cdot) : \mathbb{R}^r \mapsto \mathbb{R}$. In the above, $b(\cdot)$ is the control-dependent drift, $\sigma(\cdot)$ is the diffusion matrix, $R(\cdot)$ is the running cost, and $B(\cdot)$ is the terminal or boundary cost. Throughout the entry, we assume that the stopping time $\tau < \infty$ with probability one (w.p.1) for simplicity. Denote the value function by $V(x) = \inf_u J(x, u(\cdot))$, where the inf is taken over all admissible controls. Write the transpose of $Y \in \mathbb{R}^{d_1 \times d_2}$ as Y' with $d_1, d_2 \geq 1$, $a(x) = \sigma(x)\sigma'(x)$, and define the generator of the controlled Markov process by

$$\mathcal{L}^u f(x) = \frac{1}{2} \text{tr}(a(x) f_{xx}(x)) + b'(x, u) f_x(x), \quad (3)$$

for a suitably smooth function $f(\cdot)$, where $f_x(\cdot)$ and $f_{xx}(\cdot)$ denote the gradient and Hessian of $f(\cdot)$, respectively. Note that the operator is control dependent. Using ∂D to denote the boundary of D , then the associated Hamilton-Jacobi-Bellman (HJB) equation satisfied by the value function is given by

$$\begin{cases} \inf_u [\mathcal{L}^u V(x) + R(x, u)] = 0, & x \in D^0, \\ V(x) = B(x), & x \in \partial D. \end{cases} \quad (4)$$

The subject matter of this article is to solve the optimal stochastic control problem numerically.

The rest of the entry is arranged as follows. Section “[Markov Chain Approximation](#)” focuses on Markov chain approximation. It illustrates how one can construct the controlled Markov chain in discrete time for the approximation of the continuous-time stochastic control problems. Section “[Illustration: A One-Dimensional Problem](#)” uses a one-dimensional case as an example for illustration. Section “[Numerical](#)

Computation” discusses the implementation issues. We conclude the entry with a few further remarks.

Markov Chain Approximation

The main idea was initiated in Kushner (1977) and streamlined, extended, and further developed in Kushner and Dupuis (1992). An earlier paper describing how to discretize the elliptic HJB equation and then interpret it according to a controlled Markov chain can be found in Kushner and Kleinman (1968). This section illustrates the Markov chain approximation methods with simple setup. The reader is suggested to read the references mentioned above for a comprehensive treatment. To begin, let $h > 0$ be a small “step size” in the approximation. Instead of the domain D , we need to work with a finite set to ensure computational feasibility. Set $\mathbb{R}_h^r$ to be r -dimensional lattice cube, i.e., $\mathbb{R}_h^r = \{\dots, -2h, -h, 0, h, 2h, \dots\}^r$ (an r -dimensional product of the indicated set). Denote the interior of D by D^0 , and define $D_h^0 = D^0 \cap \mathbb{R}_h^r$.

We shall construct a controlled, discrete-time Markov chain, whose transition probabilities have desired properties in line with the controlled diffusion and whose values are in D_h^0 . Suppose that $\{\alpha_n^h\}$ is a time-homogeneous, discrete-time, controlled Markov chain with finite state space D_h^0 and transition probabilities $P = (p(x, y|v))$ with $x, y \in D_h^0$. Here we only consider the case that the Markov chain has a finite state space. This is sufficient for our computational purposes. At any time n , the control action is a random variable denoted by u_n^h taking values in a compact set U . Set the interpolation interval by $\Delta t^h(x, v) > 0$ and write $\Delta t_n^h = \Delta t^h(\alpha_n, u_n^h)$ such that $\sup_{x,v} \Delta t^h(x, v) \rightarrow 0$ as $h \rightarrow 0$ but $\inf_{x,v} \Delta t^h(x, v) > 0$ for each $h > 0$. The control is admissible if the Markov property $P(\alpha_{n+1}^h = y | \alpha_i^h, u_i^h; i \leq n) = P(\alpha_{n+1}^h = y | \alpha_n^h, u_n^h) = P(\alpha_n^h, y | u_n^h)$ holds. Use U^h to denote the collection of controls, which are determined by a sequence of measurable functions $F_n^h(\cdot)$ such that $u_n^h = F_n^h(\alpha_k^h, k \leq n; u_k^h, k < n)$. Denote the conditional expectation given $\{\alpha_j^h, u_j^h : j \leq n, \alpha_n^h = x, u_n^h = v\}$ by E_n^h . We say that a control policy is locally consistent if

$$\begin{aligned} E_n^h \alpha_n^h &= b(x, v) \Delta t^h(x, v) + o(\Delta t^h(x, v)), \\ E_n^h [\Delta \alpha_n^h - E_n^h \Delta \alpha_n^h] [\Delta \alpha_n^h - E_n^h \Delta \alpha_n^h]' &= a(x) \Delta t^h(x, v) + o(\Delta t^h(x, v)), \\ a(x) &= \sigma(x) \sigma'(x), \quad |\Delta \alpha_n^h| \rightarrow 0 \text{ as } h \rightarrow 0 \text{ uniformly in } n, \omega, \end{aligned} \quad (5)$$

where $\Delta \alpha_n^h = \alpha_{n+1}^h - \alpha_n^h$. The meaning of the local consistency can be seen from the corresponding controlled diffusion (2) (with $X(0) = x$ and $u(t) = v$ for $t \in [0, \delta]$, where $\delta > 0$ is a small parameter) in that $E_x(X(\delta) - x) = b(x, v)\delta + o(\delta)$, $E_x[X(\delta) - x][X(\delta) - x]' = a(x)\delta + o(\delta)$. Let τ_h be the first time that $\{\alpha_n^h\}$ leaves the set D_h^0 . We have an approximation for the cost function of the controlled diffusion (1) given by

$$J^h(x, u^h) = E_x^{u^h} \left[\sum_{j=0}^{\tau_h-1} R(\alpha_j^h, u_j^h) \Delta t_j^h + B(\alpha_{\tau_h}^h) \right]. \quad (6)$$

Define $t_n^h = \sum_{j=0}^{n-1} \Delta t_j^h$ and the continuous-time interpolations $\alpha^h(t) = \alpha_n^h$, $u_n^h = u_n^h$ for $t \in [t_n^h, t_{n+1}^h)$. Define the first exit time of $\alpha^h(\cdot)$ from D_h^0 by $\tau_h = t_{\tau_h}^h$. Corresponding to the continuous-time problems, the first term on the right-hand side of (6) represents the running cost and the last term gives the terminal cost. Denote the value function by $V^h(x)$. Then it satisfies the dynamic programming equation

$$V^h(x) = \begin{cases} \inf_{v \in U^h} [R(x, v) \Delta t^h(x, v) \\ + \sum_y p^h(x, y|v) V^h(y)], & x \in D_h^0, \\ B(x), & x \notin D_h^0. \end{cases} \quad (7)$$

Proving the convergence of the numerical algorithms is an important task. This requires the use of local consistency, interpolation of the approximating sequences in continuous time, as well as martingale representation. The proof is facilitated by the use of the so-called relaxed controls (Kushner and Dupuis 1992, p. 267), which enables us to characterize the limit under the framework of weak convergence. The detailed argument is beyond the scope of this entry. We refer the reader to Kushner and Dupuis (1992, Chapter 10) for further reading on the proof of convergence and the conditions needed.

Illustration: A One-Dimensional Problem

In this section, we use a one-dimensional example to illustrate the Markov chain approximation

methods, which enables us to present the results with a better visualization. Consider (2) with $x \in \mathbb{R}$. We proceed to find the transition probabilities and interpolation intervals for the Markov chain $\{\alpha_n^h\}$. To construct a controlled Markov chain that is locally consistent, we first consider a special case, namely, the control space has only one admissible control $u^h \in U^h$. In this case, min in (7) can be removed. Discretize the HJB equation using upwind finite difference method with step size $h > 0$ by

$$\begin{aligned} V(x) &\rightarrow V^h(x) \\ V_x(x) &\rightarrow \frac{V^h(x+h) - V^h(x)}{h} \text{ for } b(x, v) > 0, \\ V_x(x) &\rightarrow \frac{V^h(x) - V^h(x-h)}{h} \text{ for } b(x, v) < 0, \\ V_{xx}(x) &\rightarrow \frac{V^h(x+h) - 2V^h(x) + V^h(x-h)}{h^2}. \end{aligned}$$

For $x \in D_h^0$, it leads to

$$\begin{aligned} &\frac{V^h(x+h) - V^h(x)}{h} b^+(x, v) - \frac{V^h(x) - V^h(x-h)}{h} b^-(x, v) \\ &+ \frac{h}{2} \frac{V^h(x+h) - 2V^h(x) + V^h(x-h)}{h^2} + R(x, v) = 0, \end{aligned}$$

where b^+ and b^- are the positive and negative parts of b , respectively. Comparing with the dynamic programming equation, we obtain the transition probabilities

$$\begin{aligned} p^h(x, x+h|v) &= \frac{(a(x)/2) + hb^+(x, v)}{\tilde{\Delta}}, \\ p^h(x, x-h|v) &= \frac{(a(x)/2) + hb^-(x, v)}{\tilde{\Delta}}, \\ p^h(\cdot) &= 0, \text{ otherwise, } \Delta t^h(x, v) = \frac{h^2}{\tilde{\Delta}}, \end{aligned}$$

with $\tilde{\Delta} = a(x) + h|b(x, v)|$ being well defined. With the transition probabilities given above, we can proceed to verify the local consistency by straight forward calculations and prove the desired convergence.

Numerical Computation

To numerically approximate the controlled diffusions, frequently used methods are either value

iterations or policy iterations (iteration in policy space). Using Markov chain approximation in conjunction with either value iteration or iteration in policy space, we can further obtain a sequence of value functions $\{V^{h,n}\}$ such that $V^{h,n} \rightarrow V^h$ as $n \rightarrow \infty$. The procedures can be described as follows.

Value Iteration

1. Given a tolerance $\varepsilon > 0$, set $n = 0$; for $x \in D_h^0$, set $V^{h,0} = \text{constant}$ (for instance, 0).
2. Using $V^{h,n}$ obtained in (7) to obtain $V^{h,n+1}$.
3. If $|V^{h,n+1} - V^{h,n}| > \varepsilon$, go to Step 3 above with $n \rightarrow n + 1$.

Policy Iteration

1. Given a tolerance $\varepsilon > 0$, set $n = 0$; for $x \in D_h^0$, take an initial control $u_0^h(x) = \text{constant}$. Use $u_0^h(x)$ in lieu of v , solve (7) to find $V^{h,0}(\cdot)$.

2. Find an improved control by

$$u^{h,n+1}(x) := \operatorname{argmin}_{v \in U^h} [\sum_y p^h((x, y)|v) V^{h,n}(y) + R(x, v) \Delta t^h(x, v)].$$
3. Find $V^{h,n+1}(\cdot)$ with $u^{h,n+1}(\cdot)$ by solving (7). If $|V^{h,n+1} - V^{h,n}| > \varepsilon$, go to Step 2 above with $n \rightarrow n + 1$.

Further Remarks

Variations of the Problems. Variants of the problems can be considered. For example, one may consider nonlinear filtering problems or singularly perturbed control and filtering problems. For problems arising in manufacturing systems, one often needs to treat controlled Markov chain with no diffusion terms. Such a case can also be handled by the Markov chain approximation methods; see Sethi and Zhang (1994) for the problem and Yin and Zhang (2013, Chapter 9) for the numerical methods. In this article, we mainly discussed the approach by using probabilistic approach for getting the weak convergence of the interpolations of the controlled Markov chain. One can also use the so-called viscosity solution methods to treat the convergence; see Barles and Souganidis (1991) (also Kushner and Dupuis 1992, Chapter 11).

Variance Control. In this entry, only drift involves control term. When the diffusion term is also subject to controls, the problem becomes more difficult. In Peng (1990), the idea of using backward stochastic differential equations was initiated, which had significant impact in the development of such stochastic control problems. Detailed discussions can be found in Yong and Zhou (1999). The numerical problems for diffusion term involving controls can also be treated; see Kushner (2000) for further discussion. In this case, the so-called numerical noise or numerical viscosity can be introduced, so care must be taken.

Complex Models Involving Jump and Switching. Note that only controlled diffusions are considered in this entry. More complex models such as controlled jump diffusions (Kushner and

Dupuis 1992), switching diffusions (Yin and Zhu 2010), and switching jump diffusions can be treated (Song et al. 2006). Differential games can also be treated (Kushner 2002; Song et al. 2008).

Differential Delay Systems. Stochastic differential delay systems may come into play. The corresponding numerical algorithms have been studied extensively in Kushner (2008). Due to their inherent infinite dimensionality, a main issue here concerns suitable finite approximation to the memory segments.

Rates of Convergence. This entry mainly discusses the convergence of the approximation methods. There is also much interest in ascertaining rates of convergence. Such effort goes back to the paper Menaldi (1989) (see also Zhang 2006). Subsequently, it has been resurgent effort in dealing with this issue from a nonlinear partial differential equation point of view; see Krylov (2000). Our recent work Song and Yin (2009) complements the study by providing a probabilistic approach for treating switching diffusions.

Stochastic Approximation. In certain optimal control problems, the optimal controls or near-optimal controls turn out to be of threshold type. An alternative way of solving such problems leading to at least suboptimal or near-optimal control is to use a stochastic approximation approach; see Kushner and Yin (2003) for a comprehensive treatment of stochastic approximation algorithms. Some successful examples include manufacturing systems (Yin and Zhang 2013, Section 9.3) and liquidation decision making (Yin et al. 2002).

Numerical Methods for Nonlinear Optimal Control Problems

Lars Grüne

Mathematical Institute, University of Bayreuth,
Bayreuth, Germany

Abstract

In this article we describe the three most common approaches for numerically solving nonlinear optimal control problems governed by ordinary differential equations. For computing approximations to optimal value functions and optimal feedback laws, we present the Hamilton-Jacobi-Bellman approach. For computing approximately optimal open-loop control functions and trajectories for a single initial value, we outline the indirect approach based on Pontryagin's maximum principle and the approach via direct discretization.

Introduction

This article concerns optimal control problems governed by nonlinear ordinary differential equations of the form

$$\dot{x}(t) = f(x(t), u(t)) \quad (1)$$

with $f : \mathbb{R} \times \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$. We assume that for each initial value $x \in \mathbb{R}^n$ and measurable control function $u(\cdot) \in L^\infty(\mathbb{R}, \mathbb{R}^m)$, there exists a unique solution $x(t) = x(t, x, u(\cdot))$ of (1) satisfying $x(0, x, u(\cdot)) = x$.

Given a state constraint set $X \subseteq \mathbb{R}^n$ and a control constraint set $U \subseteq \mathbb{R}^m$, a running cost $g : X \times U \rightarrow \mathbb{R}$, a terminal cost $F : X \rightarrow \mathbb{R}$, and

a discount rate $\delta \geq 0$, we consider the optimal control problem

$$\text{minimize } J^T(x, u(\cdot)) \quad (2)$$

$$u(\cdot) \in \mathcal{U}^T(x)$$

where

$$J^T(x, u(\cdot)) := \int_0^T e^{-\delta s} g(x(s, x, u(\cdot)), u(s)) ds$$

$$+ e^{-\delta T} F(x(T, x, u(\cdot))) \quad (3)$$

and

$$\mathcal{U}^T(x) := \left\{ u(\cdot) \in L^\infty(\mathbb{R}, U) \mid \begin{array}{l} x(s, x, u(\cdot)) \in X \\ \text{for all } s \in [0, T] \end{array} \right\}. \quad (4)$$

In addition to this finite horizon optimal control problem, we also consider the infinite horizon problem in which T is replaced by “ ∞ ,” i.e.,

$$\text{minimize } J^\infty(x, u(\cdot)) \quad (5)$$

$$u(\cdot) \in \mathcal{U}^\infty(x)$$

where

$$J^\infty(x, u(\cdot)) := \int_0^\infty e^{-\delta s} g(x(s, x, u(\cdot)), u(s)) ds \quad (6)$$

and

$$\mathcal{U}^\infty(x) := \left\{ u(\cdot) \in L^\infty(\mathbb{R}, U) \mid \begin{array}{l} x(s, x, u(\cdot)) \in X \\ \text{for all } s \geq 0 \end{array} \right\}, \quad (7)$$

respectively.

The term “solving” (2), (3), (4) or (5), (6), (7) can have various meanings. First, the optimal value functions

$$V^T(x) = \inf_{u(\cdot) \in \mathcal{U}^T(x)} J^T(x, u(\cdot))$$

or

$$V^\infty(x) = \inf_{u(\cdot) \in \mathcal{U}^\infty(x)} J^\infty(x, u(\cdot))$$

may be of interest. Second, and often more importantly, one would like to know the optimal

control policy. This can be expressed in *open-loop* form $u^* : \mathbb{R} \rightarrow U$, in which the function u^* depends on the initial value x and on the initial time which we set to 0 here. Alternatively, the optimal control can be computed in state- and time-dependent *closed-loop* form, in which a feedback law $\mu^* : \mathbb{R} \times X \rightarrow U$ is sought. Via $u^*(t) = \mu^*(t, x(t))$, this feedback law can then be used in order to generate the time-dependent optimal control function for all possible initial values. Since the feedback law is evaluated along the trajectory, it is able to react to perturbations and uncertainties which may make $x(t)$ deviate from the predicted path. Finally, knowing u^* or μ^* , one can reconstruct the corresponding optimal trajectory by solving

$$\begin{aligned}\dot{x}(t) &= f(x(t), u^*(t)) \quad \text{or} \\ \dot{x}(t) &= f(x(t), \mu^*(t, x(t))).\end{aligned}$$

Hamilton-Jacobi-Bellman Approach

In this section we describe the numerical approach to solving optimal control problems via Hamilton-Jacobi-Bellman equations. We first describe how this approach can be used in order to compute approximations to the optimal value function V^T and V^∞ , respectively, and afterwards how the optimal control can be synthesized using these approximations. In order to formulate this approach for finite horizon T , we interpret $V^T(x)$ as a function in T and x . We denote differentiation with respect to T and x with subscript T and x , i.e., $V_x^T(x) = dV^T(x)/dx$, $V_T^T(x) = dV^T(x)/dT$, etc.

We define the Hamiltonian of the optimal control problem as

$$H(x, p) := \max_{u \in U} \{-g(x, u) - p \cdot f(x, u)\},$$

with $x, p \in \mathbb{R}^n$, f from (1), g from (3) or (6), and “ $\cdot$ ” denoting the inner product in $\mathbb{R}^n$. Then, under appropriate regularity conditions on the problem data, the optimal value functions V^T and V^∞

satisfy the first order partial differential equations (PDEs)

$$V_T^T(x) + \delta V^T(x) + H(x, V_x^T(x)) = 0$$

and

$$\delta V^\infty(x) + H(x, V_x^\infty(x)) = 0$$

in the viscosity solution sense. In the case of V^T , the equation holds for all $T \geq 0$ with the boundary condition $V^0(x) = F(x)$.

The framework of viscosity solutions is needed because in general the optimal value functions will not be smooth; thus, a generalized solution concept for PDEs must be employed (see Bardi and Capuzzo Dolcetta 1997). Of course, appropriate boundary conditions are needed at the boundary of the state constraint set X .

Once the Hamilton-Jacobi-Bellman characterization is established, one can compute numerical approximations to V^T or V^∞ by solving these PDEs numerically. To this end, various numerical schemes have been suggested, including various types of finite element and finite difference schemes. Among those, semi-Lagrangian schemes, see Falcone (1997) or Falcone and Ferretti (2013), allow for a particularly elegant interpretation in terms of optimal control synthesis, which we explain for the infinite horizon case.

In the semi-Lagrangian approach, one takes advantage of the fact that by the chain rule for $p = V_x^\infty(x)$ and constant control functions u , the identity

$$\begin{aligned}\delta V^\infty(x) - p \cdot f(x, u) &= \left. \frac{d}{dt} \right|_{t=0} \\ &\quad - (1 - \delta t) V^\infty(x(t, x, u))\end{aligned}$$

holds. Hence, the left-hand side of this equality can be approximated by the difference quotient

$$\frac{V^\infty(x) - (1 - \delta h) V^\infty(x(h, x, u))}{h}$$

for small $h > 0$. Inserting this approximation into the Hamilton-Jacobi-Bellman equation, replacing $x(h, x, u)$ by a numerical approximation

$\tilde{x}(h, x, u)$ (in the simplest case, the Euler method $\tilde{x}(h, x, u) = x + hf(x, u)$), multiplying by h , and rearranging terms, one arrives at the equation

$$V_h^\infty(x) = \min_{u \in U} \left\{ hg(x, u) + (1 - \delta h) V_h^\infty(\tilde{x}(h, x, u)) \right\}$$

defining an approximation $V_h^\infty \approx V^\infty$. This is now a purely algebraic dynamic programming-type equation which can be solved numerically, e.g., by using a finite element approach. The equation is typically solved iteratively using a suitable minimization routine for computing the “min” in each iteration (in the simplest case, U is discretized with finitely many values, and the minimum is determined by direct comparison). We denote the resulting approximation of V^∞ by $\tilde{V}_h^\infty$. Here, approximation is usually understood in the L^∞ sense (see Falcone 1997 or Falcone and Ferretti 2013).

The semi-Lagrangian scheme is appealing for synthesis of an approximately optimal feedback because V_h^∞ is the optimal value function of the auxiliary discrete-time problem defined by $\tilde{x}$. This implies that the expression

$$\mu_h^*(x) := \operatorname{argmin}_{u \in U} \left\{ hg(x, u) + (1 - \delta h) V_h^\infty(\tilde{x}(h, x, u)) \right\},$$

is an optimal feedback control value for this discrete-time problem for the next time step, i.e., on the time interval $[t, t + h]$ if $x = x(t)$. This feedback law will be approximately optimal for the continuous-time control system when applied as a discrete-time feedback law, and this approximate optimality remains true if we replace V_h^∞ in the definition of μ_h^* by its numerically computable approximation $\tilde{V}_h^\infty$. A similar construction can be made based on any other numerical approximation $\tilde{V}^\infty \approx V^\infty$, but the explicit correspondence of the semi-Lagrangian scheme to a discrete-time auxiliary system facilitates the

interpretation and error analysis of the resulting control law.

The main advantage of the Hamilton-Jacobi approach is that it directly computes an approximately optimal feedback law. Its main disadvantage is that the number of grid nodes needed for maintaining a given accuracy in a finite element approach to compute $\tilde{V}_h^\infty$ in general grows exponentially with the state dimension n . This fact – known as the *curse of dimensionality* – restricts this method to low-dimensional state spaces. Unless special structure is available which can be exploited, as, e.g., in the max-plus approach (see McEneaney 2006), it is currently almost impossible to go beyond state dimensions of about $n = 10$, typically less for strongly nonlinear problems.

Maximum Principle Approach

In contrast to the Hamilton-Jacobi-Bellman approach, the approach via Pontryagin’s maximum principle does not compute a feedback law. Instead, it yields an approximately open-loop optimal control u^* together with an approximation to the optimal trajectory x^* for a fixed initial value. We explain the approach for the finite horizon problem. For simplicity of presentation, we omit state constraints in our presentation, i.e., we set $X = \mathbb{R}^n$ and refer to, e.g., Vinter (2000), Bryson and Ho (1975), or Grass et al. (2008) for more general formulations as well as for rigorous versions of the following statements.

In order to state the maximum principle (which, since we are considering a minimization problem here, could also be called minimum principle), we define the non-minimized Hamiltonian as

$$\mathcal{H}(x, p, u) = g(x, u) + p \cdot f(x, u).$$

Then, under appropriate regularity assumptions, there exists an absolutely continuous function $p : [0, T] \rightarrow \mathbb{R}^n$ such that the optimal trajectory x^* and the corresponding optimal control function u^* for (2), (3) and (4) satisfy

$$\dot{p}(t) = \delta p(t) - \mathcal{H}_x(x^*(t), p(t), u^*(t)) \quad (8)$$

with terminal or transversality condition

$$p(T) = F_x(x^*(T)) \quad (9)$$

and

$$u^*(t) = \operatorname{argmin}_{u \in U} \mathcal{H}(x^*(t), p(t), u), \quad (10)$$

for almost all $t \in [0, T]$ (see Grass et al. 2008, Theorem 3.4). The variable p is referred to as the *adjoint* or *costate* variable.

For a given initial value $x_0 \in \mathbb{R}^n$, the numerical approach now consists of finding functions $x : [0, T] \rightarrow \mathbb{R}^n$, $u : [0, T] \rightarrow U$ and $p : [0, T] \rightarrow \mathbb{R}^n$ satisfying

$$\dot{x}(t) = f(x(t), u(t)) \quad (11)$$

$$\dot{p}(t) = \delta p(t) - \mathcal{H}_x(x(t), p(t), u(t)) \quad (12)$$

$$u(t) = \operatorname{argmin}_{u \in U} \mathcal{H}(x(t), p(t), u) \quad (13)$$

$$x(0) = x_0, \quad p(T) = F_x(x(T)) \quad (14)$$

for $t \in [0, T]$. Depending on the regularity of the underlying data, the conditions (11), (12), (13) and (14) may only be necessary but not sufficient for x and u being an optimal trajectory x^* and control function u^* , respectively. However usually x and u satisfying these conditions, are good candidates for the optimal trajectory and control, thus justifying the use of these conditions for the numerical approach. If needed, optimality of the candidates can be checked using suitable sufficient optimality conditions for which we refer to, e.g., Maurer (1981) or Malanowski et al. (2004). Due to the fact that in the maximum principle approach first optimality conditions are derived which are then discretized for numerical simulation, it is also termed *first optimize then discretize*.

Solving (11), (12), (13) and (14) numerically amounts to solving a boundary value problem, because the condition $x^*(0) = x_0$ is posed at the beginning of the time interval $[0, T]$, while the condition $p(T) = F_x(x^*(T))$ is required at

the end. In order to solve such a problem, the simplest approach is the *single shooting* method which proceeds as follows:

We select a numerical scheme for solving the ordinary differential equations (11) and (12) for $t \in [0, T]$ with initial conditions $x(0) = x_0$, $p(0) = p_0$ and control function $u(t)$. Then, we proceed iteratively as follows:

- (0) Find initial guesses $p_0^0 \in \mathbb{R}^n$ and $u^0(t)$ for the initial costate and the control, fix $\varepsilon > 0$, and set $k := 0$.
- (1) Solve (11) and (12) numerically with initial values x_0 and p_0^k and control function u^k . Denote the resulting trajectories by $\tilde{x}^k(t)$ and $\tilde{p}^k(t)$.
- (2) Apply one step of an iterative method for solving the zero-finding problem $G(p) = 0$ with

$$G(p_0^k) := \tilde{p}^k(T) - F_x(\tilde{x}^k(T))$$

for computing p_0^{k+1} . For instance, in case of the Newton method we get

$$p_0^{k+1} := p_0^k - DG(p_0^k)^{-1}G(p_0^k).$$

If $\|p_0^{k+1} - p_0^k\| < \varepsilon$, stop; else compute

$$u^{k+1}(t) := \operatorname{argmin}_{u \in U} \mathcal{H}(\tilde{x}^k(t), \tilde{p}^k(t), u),$$

set $k := k + 1$, and go to (1).

The procedure described in this algorithm is called *single shooting* because the iteration is performed on the single initial value p_0^k . For an implementable scheme, several details still need to be made precise, e.g., how to parameterize the function $u(t)$ (e.g., piecewise constant, piecewise linear or polynomial), how to compute the derivative DG and its inverse (or an approximation thereof), and the argmin in (2). The last task considerably simplifies if the structure of the optimal control, e.g., the number of switchings in case of a bang-bang control, is known.

However, even if all these points are settled, the set of initial guesses p_0^0 and u^0 for which the method is going to converge to a solution of (11), (12), (13) and (14) tends to be very small. One reason for this is that the solutions of (11) and (12) typically depend very sensitively on p_0^0 and u^0 . In order to circumvent this problem, *multiple shooting* can be used. To this end, one selects a time grid $0 = t_0 < t_1 < t_2 < \dots < t_N = T$ and in addition to p_0^k introduces variables $x_1^k, \dots, x_{N-1}^k, p_1^k, \dots, p_{N-1}^k \in$

$\mathbb{R}^n$. Then, starting from initial guesses p_0^0, u^0 , and $x_1^0, \dots, x_{N-1}^0, p_1^0, \dots, p_{N-1}^0$, in each iteration the Eqs. (11), (12), (13) and (14) are solved numerically on the intervals $[t_j, t_{j+1}]$ with initial values x_j^k and p_j^k , respectively. We denote the respective solutions in the k -th iteration by $\tilde{x}_j^k$ and $\tilde{p}_j^k$. In order to enforce that the trajectory pieces computed on the individual intervals $[t_j, t_{j+1}]$ fit together continuously, the map G is redefined as

$$G(x_1^k, \dots, x_{N-1}^k, p_0^k, p_1^k, \dots, p_{N-1}^k) = \begin{pmatrix} \tilde{x}_0^k(t_1) - x_1^k \\ \vdots \\ \tilde{x}_{N-2}^k(t_1) - x_{N-1}^k \\ \tilde{p}_0^k(t_1) - p_1^k \\ \vdots \\ \tilde{p}_{N-2}^k(t_1) - p_{N-1}^k \\ \tilde{p}_{N-1}^k(T) - F_x(\tilde{x}_{N-1}^k(T)) \end{pmatrix}.$$

The benefit of this approach is that the solutions on the shortened time intervals depend much less sensitively on the initial values and the control, thus making the problem numerically much better conditioned. The obvious disadvantage is that the problem becomes larger as the function G is now defined on a much higher dimensional space, but this additional effort usually pays off.

While the convergence behavior for the multiple shooting method is considerably better than for single shooting, it is still a difficult task to select good initial guesses x_j^0, p_j^0 and u^0 . In order to accomplish this, homotopy methods can be used (see, e.g., Pesch 1994), or the result of a direct approach as presented in the next section can be used as an initial guess. The latter can be reasonable as the maximum principle-based approach can yield approximations of higher accuracy than the direct method.

In the presence of state constraints or mixed state and control constraints, the conditions (12), (13) and (14) become considerably more technical and thus more difficult to be implemented numerically (cf. Pesch 1994).

Direct Discretization

Despite being the most straightforward and simple of the approaches described in this article, the direct discretization approach is currently the most widely used approach for computing single finite horizon optimal trajectories. In the direct approach, we first discretize the problem and then solve a finite dimensional nonlinear optimization problem (NLP), i.e., we *first discretize, then optimize*. The main reasons for the popularity of this approach are the simplicity with which constraints can be handled and the numerical efficiency due to the availability of fast and reliable NLP solvers.

The direct approach again applies to the finite horizon problem and computes an approximation to a single optimal trajectory $x^*(t)$ and control function $u^*(t)$ for a given initial value $x_0 \in X$. To this end, a time grid $0 = t_0 < t_1 < t_2 < \dots < t_N = T$ and a set $\mathcal{U}_d$ of control functions which are parameterized by finitely many values are selected. The simplest way to do so is to choose $u(t) \equiv u_j \in U$ for all $t \in [t_i, t_{i+1}]$. However, other approaches like piecewise linear

or piecewise polynomial control functions are possible, too. We use a numerical algorithm for ordinary differential equations in order to approximately solve the initial value problems

$$\dot{x}(t) = f(x(t), u_i), \quad x(t_i) = x_i \quad (15)$$

for $i = 0, \dots, N-1$ on $[t_i, t_{i+1}]$. We denote the exact and numerical solution of (15) by $x(t, t_i, x_i, u_i)$ and $\tilde{x}(t, t_i, x_i, u_i)$, respectively. Finally, we choose a numerical integration rule in order to compute an approximation

$$I(t_i, t_{i+1}, x_i, u_i) \approx \int_{t_i}^{t_{i+1}} e^{-\delta t} g(x(t, t_i, x_i, u), u(t)) dt.$$

In the simplest case, one might choose $\tilde{x}$ as the Euler scheme and I as the rectangle rule, leading to

$$\tilde{x}(t_{i+1}, t_i, x_i, u_i) = x_i + (t_{i+1} - t_i) f(x_i, u_i)$$

and

$$I(t_i, t_{i+1}, x_i, u_i) = (t_{i+1} - t_i) e^{-\delta t_i} g(x_i, u_i).$$

Introducing the optimization variables $u_0, \dots, u_{N-1} \in \mathbb{R}^m$ and $x_1, \dots, x_N \in \mathbb{R}^n$, the discretized version of (2), (3) and (4) reads

$$\underset{x_j \in \mathbb{R}^n, u_j \in \mathbb{R}^m}{\text{minimize}} \sum_{i=0}^{N-1} I(t_i, t_{i+1}, x_i, u) + e^{-\delta T} F(x_N)$$

subject to the constraints

$$\begin{aligned} u_j &\in U, & j &= 0, \dots, N-1 \\ x_j &\in X, & j &= 1, \dots, N \\ x_{j+1} &= \tilde{x}(t_{j+1}, t_j, x_j, u), & j &= 0, \dots, N \end{aligned}$$

This way, we have converted the optimal control problem (2), (3) and (4) into a finite dimensional nonlinear optimization problem (NLP). As such, it can be solved with any numerical method for solving such problems. Popular methods are, for instance, sequential quadratic

programming (SQP) or interior point (IP) algorithms. The convergence of this approach was proved in Malanowski et al. (1998); for an up-to-date account on theory and practice of the method; see Gerds (2012) and Betts (2010). These references also explain how information about the costates $p(t)$ can be extracted from a direct discretization, thus linking the approach to the maximum principle.

The direct method sketched here is again a multiple shooting method, and the benefit of this approach is the same as for solving boundary problems: thanks to the short intervals $[t_i, t_{i+1}]$, the solutions depend much less sensitively on the data than the solution on the whole interval $[0, T]$, thus making the iterative solution of the resulting discretized NLP much easier. The price to pay is again the increase of the number of optimization variables. However, due to the particular structure of the constraints guaranteeing continuity of the solution, the resulting matrices in the NLP have a particular structure which can be exploited numerically by a method called *condensing* (see Bock and Plitt 1984).

An alternative to multiple shooting is collocation, in which the internal variables of the numerical algorithm for solving (15) are also optimization variables. A popular subclass of these algorithms are pseudospectral methods, in which Gauss quadrature points are used for the collocation; see Garg et al. (2010). However, nowadays, the multiple shooting approach as described above is often preferred. For a more detailed description of various direct approaches, see also Binder et al. (2001), Sect. 5.

Further Approaches for Infinite Horizon Problems

The last two approaches only apply to finite horizon problems. While the maximum principle approach can be generalized to infinite horizon problems, the necessary conditions become weaker, and the numerical solution becomes considerably more involved (see Grass et al. 2008). Both the maximum principle and the direct approach can, however, be applied in a

receding horizon fashion, in which an infinite horizon problem is approximated by the iterative solution of finite horizon problems. The resulting control technique is known under the name of model predictive control (MPC; see Grüne and Pannek 2017). Under suitable assumptions, in which the classical turnpike property of optimal control problems plays an important role, rigorous approximation results can be established.

Summary and Future Directions

The three main numerical approaches to optimal control are:

- The Hamilton-Jacobi-Bellman approach, which provides a global solution in feedback form but is computationally expensive for higher dimensional systems
- The Pontryagin maximum principle approach which computes single optimal trajectories with high accuracy but needs good initial guesses for the iteration
- The direct approach which also computes single optimal trajectories but is less demanding in terms of the initial guesses at the expense of a somewhat lower accuracy

Currently, the main trends in numerical optimal control lie in the areas of Hamilton-Jacobi-Bellman equations and direct discretization. For the former, the development of discretization schemes suitable for increasingly higher dimensional problems is in the focus. For the latter, the popularity of these methods in online applications like MPC triggers continuing effort to make this approach faster and more reliable.

Beyond ordinary differential equations, the development of numerical algorithms for the optimal control of partial differential equations (PDEs) has attracted considerable attention during the last years. While many of these methods are still restricted to linear systems, in the near future, we can expect to see many extensions to (classes of) nonlinear PDEs. It is

worth noting that for PDEs, first-optimize-then-discretize approaches are more popular than for ordinary differential equations.

Observer-Based Control

H.L. Trentelman¹ and Panos J. Antsaklis²

²Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

An observer-based controller is a dynamic feedback controller with a two-stage structure. First, the controller generates an estimate of the state variable of the system to be controlled, using the measured output and known input of the system. This estimate is generated by a state observer for the system. Next, the state estimate is treated as if it were equal to the exact state of the system, and it is used by a static state feedback controller. Dynamic feedback controllers with this two-stage structure appear in various control synthesis problems for linear systems. In this entry, we explain observer-based control in the context of internal stabilization by dynamic measurement feedback.

principle · Stabilizability · State observers · Static state feedback

Introduction

In this entry, we explain the notion of observer-based feedback control. Given a to-be-controlled system in input-state-output form, together with a control objective, the problem is to design a feedback controller such that the closed-loop system meets the objective. In the case when all state variables of the system are available for control, the design problem is considered to be simpler, and often the controller can be chosen to be a static state feedback control law. In the more general case where the controller has access only to a linear function of the state variables, the problem is more involved and requires the design of a dynamic feedback control law. The key idea of observer-based feedback control is the following. As a first step, one determines a state observer for the system, i.e., a system that estimates the state of the system based on the measured outputs and inputs of the system. Next, the state estimate is treated as if it were exactly equal to the actual state of the system and is used by a static state feedback controller. In this way, a dynamic feedback controller is obtained that is composed of a (dynamic) state observer and a static feedback part.

Dynamic Output Feedback Control

Consider the controlled and observed system Σ :

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) + Ed(t), \\ y(t) &= Cx(t), \\ z(t) &= Hx(t),\end{aligned}\tag{1}$$

with $x(t) \in \mathcal{X} = \mathbb{R}^n$ the state, $u(t) \in \mathbb{R}^m$ the control input, and $y(t) \in \mathbb{R}^p$ the measured output. The signal $d(t)$ may represent a disturbance input or a desired reference signal, while the signal $z(t)$ is a controlled output signal. A , B , C , E , and H are maps (or matrices). In general, a linear controller for this system is a finite-dimensional linear time-invariant system Γ represented by

$$\begin{aligned}\dot{w}(t) &= Kw(t) + Ly(t), \\ u(t) &= Mw(t) + Ny(t).\end{aligned}\tag{2}$$

The state space of the controller is assumed to be $\mathcal{W} = \mathbb{R}^q$ for some positive integer q . K , L , M , and N are assumed to be linear maps (or matrices). The controller (2) takes the observations y as its input and generates the control function u as its output. The closed-loop system resulting from the interconnection of Σ and Γ is described by the equations

$$\begin{aligned}\begin{pmatrix} \dot{x}(t) \\ \dot{w}(t) \end{pmatrix} &= \begin{pmatrix} A+BNC & BM \\ LC & K \end{pmatrix} \begin{pmatrix} x(t) \\ w(t) \end{pmatrix} + \begin{pmatrix} E \\ 0 \end{pmatrix} d(t), \\ z(t) &= \begin{pmatrix} H & 0 \end{pmatrix} \begin{pmatrix} x(t) \\ z(t) \end{pmatrix}.\end{aligned}\tag{3}$$

The control action of interconnecting the controller Γ with the system (1) is called *dynamic feedback*. The state space of the closed-loop system (3) is called the *extended state space* and is equal to the Cartesian product $\mathcal{X} \times \mathcal{W} = \mathbb{R}^{n+q}$. In general, a feedback control problem amounts to finding linear maps K , L , M , and N such that the closed-loop system (3) satisfies the control design specifications.

Observer-Based Controllers

Given the system (1) and a control objective, the problem thus arises on how to determine the maps K , L , M , and N so that the closed-loop systems meet the objective. As an example, take the special case when E in (1) is equal to zero (i.e., the system has no external disturbances or reference signals) and that we wish the closed-loop system (3) to be internally stable, i.e., we want to find the maps K , L , M , and N so that the eigenvalues λ_i of the system map of (3) are in the open left half-plane, i.e., satisfy $\text{Re}(\lambda_i) < 0$ for all i . If we had access to the entire state variable x (instead of only to the linear function $y = Cx$), then this problem would be simpler: assuming that the system is stabilizable (The system $\dot{x} = Ax + Bu$ is called stabilizable if there exists a map F such that $A + BF$ has all its eigenvalues in the open left half-plane), find a map F such that the eigenvalues of $A + BF$ are in the open left half-plane; then take the static state feedback controller $u = Fx$ as the control law. That is, we would choose the state space dimension of the controller Γ equal to 0 and the maps K , L , and M to be void, and we would take $N = F$.

In general, however, we only have access to a given linear function $y = Cx$ of x , determined by the output map C . The key idea of observer-based control is the following:

Use the theory of observer design to find an observer for the state x of the system (1), i.e., an observer that generates an estimate ξ of the system state x based on the measured output y and the control input u . Next, apply a static feedback $u = F\xi$ mimicking the (not permissible) control law $u = Fx$.

This idea leads to a dynamic feedback controller (2) of a very particular structure: the controller is the combination of a state observer (with a certain state space dimension) and a static control law acting on the state estimate. This *two-stage* structure, separating estimation and control, is often called the *separation principle*. We will work out this idea in more detail for the case when $E = 0$ (no external disturbances or reference signals) and the aim is to obtain internal

stability of the system. Before doing this, we first explain the most important material on observers that is needed in the sequel.

State Observers

If the state is not available for measurement, one can try to reconstruct it using a system, called observer, that takes the control input and the measured output of the original system as inputs and yields an output that is an estimate of the state of the original system. Again in case that in the system (1) we have $E = 0$, i.e., there are no disturbance signals. This is illustrated in the following picture:

The quantity ξ is supposed to be an estimate, in some sense, of the state, and w is the state variable of the observer. In general, the observer, denoted by Ω , has equations of the form

$$\begin{aligned}\dot{w}(t) &= Pw(t) + Qu(t) + Ry(t), \\ \xi(t) &= Sw(t).\end{aligned}\quad (4)$$

It turns out that particular choices for P , Q , R , and S , specifically $P = A - GC$ (where the map G has to be determined), $Q = B$, $R = G$, and $S = I$, lead to

$$\dot{\xi}(t) = (A - GC)\xi(t) + Bu(t) + Gy(t). \quad (5)$$

Introducing the *estimation error* $e := \xi - x$ and interconnecting the system (1) with (5), we find that the error e satisfies the differential equation

$$\dot{e}(t) = (A - GC)e(t). \quad (6)$$

Hence all possible errors converge to 0 as t tends to infinity if and only if $A - GC$ is a stability matrix, i.e., has all its eigenvalues in the open left half-plane. In that case, we call (5) a *stable state observer*. Thus, a stable state observer exists if and only if G can be found such that $A - GC$ is a stability matrix. The problem of finding such a G is dual to the problem of finding a matrix F to a pair (A, B) such that $A + BF$ is a stability matrix.

Definition 1 The pair (C, A) is called *detectable* if there exists a matrix G such that $A - GC$ is a stability matrix, i.e., has all its eigenvalues in the open left half-plane.

Theorem 1 Given system Σ , the following statements are equivalent:

1. Σ has a stable state observer.
2. (C, A) is detectable.

The equation for ξ can be rewritten using an artificial output $\eta = C\xi$ as $\dot{\xi} = A\xi + Bu + G(y - \eta)$. The interpretation of this is as follows. If ξ is the exact state, then $\eta = y$, and hence ξ obeys exactly the same differential equation as x . Otherwise, the equation for ξ has to be corrected by a term determined by the *output error* $y - \eta$. Consequently, the state observer consists of an exact replica Σ_{dup} of the original system with an extra input channel for incorporating the output error and an extra output, the state of the observer, which serves as the desired estimate for the state of the original system. The following diagram depicts the situation:

Observer-Based Stabilization

We now work out the ideas put forward in the previous sections for the special case of stabilization by dynamic measurement feedback, i.e., to find a controller (2) such that the closed-loop system (3) is internally stable; equivalently, the system mapping of (3) is a stability matrix. Again, we restrict ourselves to the case when $E = 0$.

We assume that we know how to stabilize by state feedback and how to build a state observer. If we have a plant of which we do not have the state available for measurement, we use a state observer to obtain an estimate of the state, and we apply the state feedback to this estimate rather than to the true state. This is illustrated by the following picture:

Again, consider the system Σ given by (1) and let the observer Ω be given by (5). Combining this with $u = F\xi$ yields

$$\begin{aligned}\dot{x}(t) &= Ax(t) + BF\xi, \\ \dot{\xi}(t) &= (A - GC + BF)\xi(t) + GCx(t).\end{aligned}\quad (7)$$

Introducing again $e := \xi - x$, we obtain, in accordance with the previous section,

$$\begin{aligned}\dot{x}(t) &= (A + BF)x(t) + BFe(t), \\ \dot{e}(t) &= (A - GC)e(t).\end{aligned}$$

That is, the equation $\dot{x}_e = A_e x_e$ with

$$x_e := \begin{pmatrix} x \\ e \end{pmatrix}, \quad A_e := \begin{pmatrix} A + BF & BF \\ 0 & A - GC \end{pmatrix}.$$

Assume that Σ is stabilizable and detectable. Then F and G can be found such that $A + BF$ and $A - GC$ are stability matrices. Since the set of eigenvalues of A_e is the union of those of $A + BF$ and $A - GC$, it follows that A_e is a stability matrix. Consequently, the system $\dot{x}_e = A_e x_e$ is asymptotically stable; equivalently, every solution $x_e = (x, e)$ converges to 0 as t tends to infinity. Of course, if (x, ξ) is a solution of (7), then $\xi = x + e$, with $x_e = (x, e)$ a solution of $\dot{x}_e = A_e x_e$. Hence (x, ξ) also converges to 0 as t goes to infinity. Thus we have proved the “if” part of the following theorem:

Theorem 2 *There exists an internally stabilizing dynamic feedback controller for Σ if and only if Σ is stabilizable and detectable. A controller is given by*

$$\begin{aligned}\dot{\xi}(t) &= (A - GC)\xi(t) + Bu(t) + Gy(t), \\ u(t) &= F\xi(t),\end{aligned}\quad (8)$$

where F is any map such that $A + BF$ is a stability matrix and G is any map such that $A - GC$ is a stability matrix.

The controller (8) is an *observer-based dynamic feedback controller*, since it is composed of a state observer and a static feedback part.

Summary and Future Directions

We have given an introduction to observer-based feedback controllers and have explained that such controllers are dynamic feedback controllers that can be represented as the composition of a state observer for the system, together with a static control law mimicking a (not permitted) static state feedback control law. We have given a detailed description of this principle for the case that the system to be controlled has no external disturbances or reference signals and the control objective is internal stability of the system. More intricate versions of the principle of observer-based feedback control appear in control design problems for linear systems with external disturbances and reference signals and with different, more sophisticated, control objectives. Examples

of these are the regulator problem, the problem of disturbance decoupling with internal stability, the $\mathcal{H}_2$ optimal control problem, and the $\mathcal{H}_\infty$ suboptimal control problem.

Observers for Nonlinear Systems

Laurent Praly
MINES ParisTech, PSL, Fontainebleau, France

Abstract

Observers are objects delivering estimation of variables which cannot be directly measured. The access to such *hidden* variables is made possible by combining modeling and measurements. But this is bringing face to face real world and its abstraction with, as a result, the need for dealing with uncertainties and approximations leading to difficulties in implementation and convergence.

Keywords

Estimation · Distinguishability · Detectability

Introduction

Observers are answers to the question of estimating, from observed/measured/empirical variables, denoted y , and delivered by sensors equipping a real world system, some “theoretical” variables, called hidden variables in this text, denoted z , which are involved in a mathematical model related to this system. The measured variables make what is called the a posteriori information on the hidden variables, whereas the model is part of the a priori information. Because a model cannot fit exactly a system, introduction of uncertainties is mandatory.

Typically this model describing the link between hidden and measured variables is made of three components:

- *a dynamic model* describes the dynamics/evolution ($\dot{x}$ denotes the time derivative $\frac{dx}{dt}$):

$$\begin{aligned}\dot{x}(t) &= f(x(t), t, \delta^s(t)) \quad \text{resp.} \\ x_{k+1} &= f_k(x_k, \delta_k^s),\end{aligned}\tag{1}$$

where t , in the continuous case, or k , in the discrete case, is an evolution parameter, called time in this text; x is a state, assumed finite dimensional in this text; and δ^s represents the uncertainties in the state dynamics. Any possible known inputs is represented here by the time-dependence of f .

- *a sensor model* relates state and measured variables:

$$\begin{aligned}y(t) &= h(x(t), t, \delta^m(t)) \quad \text{resp.} \\ y_k &= h_k(x_k, \delta_k^m)\end{aligned}\tag{2}$$

with δ_k^m representing the uncertainties in the measurements.

- a model which relates state and hidden variables:

$$\begin{aligned}z(t) &= \eta(x, t, \delta^h(t)) \quad \text{resp.} \\ z_k &= \eta_k(x_k, \delta_k^h).\end{aligned}\tag{3}$$

where again δ^h represents the uncertainties in the hidden variables.

In a deterministic setting, the a priori information on the uncertainties ($\delta^s, \delta^m, \delta^h$) may be that the values of δ^s, δ^m and δ^h are unknown but belong to known sets Δ^s, Δ^m and Δ^h . Namely, we have:

$$\begin{aligned} \delta^s(t) &\in \Delta^s(t), \quad \delta^m(t) \in \Delta^m(t), \quad \delta^h(t) \in \Delta^h(t), \\ \text{respectively} \quad \delta_k^s &\in \Delta_k^s, \quad \delta_k^m \in \Delta_k^m, \quad \delta_k^h \in \Delta_k^h. \end{aligned} \quad (4)$$

In a stochastic setting and more specifically in a Bayesian approach, it may be that δ^s, δ^m and δ^h are unknown realization of stochastic processes for which we know the probability distributions.

Similarly we may also know a priori that we have:

$$\begin{aligned} x(t) &\in \mathcal{X}(t), \quad z(t) \in \mathcal{Z}(t) \\ \text{respectively} \quad x_k &\in \mathcal{X}_k, \quad z_k \in \mathcal{Z}_k \end{aligned} \quad (5)$$

where the sets $\mathcal{X}$ and $\mathcal{Z}$ are known or we may have a priori probability distribution for x and z .

In this context, the a priori information is the data of the functions f, h , and q , of the sets $\Delta^s, \Delta^m, \Delta^h$ or the corresponding probability distribution and so maybe also of the sets $\mathcal{X}$ and $\mathcal{Z}$ or the corresponding a priori probability distribution.

In the next section, we state the observation problem and give the solutions which are direct consequences of the deterministic and stochastic setting given above. This will allow us to see that an observer is actually a dynamical system with the measurements as inputs and the estimate as output. But approximations in the implementation of these solutions, not knowing how to initialize, ... may lead to convergence problems even when the uncertainties disappear. The second part of this text is devoted to this convergence topic.

To ease the presentation we deal only with the discrete time case in section “[Set Valued and Conditional Probability Valued Observers](#)”, and the continuous time case in sections

“[An Optimization Approach](#)” and “[Convergent Observers](#)”.

Observation Problem and Its Solutions

The Observation Problem

Let $X^{\delta^s}(x, t, s)$, respectively $X_l^{\delta^s}(x, k)$, denote a solution of (1) at time s , respectively l , going through x at time t , respectively k , and under the action of δ^s .

Observation problem *At each time t , respectively k , given the function $s \in]t - T, t] \mapsto y(s)$, respectively the sequence $l \in \{k - K, \dots, k\} \mapsto y_l$, find an estimation $\hat{z}(t)$, respectively $\hat{z}_k$, of $z(t)$, respectively z_k , satisfying:*

$$\begin{aligned} \hat{z}(t) &= q(\hat{x}(t), t, \delta^h(t)) \quad \text{resp.} \\ \hat{z}_k &= q_k(\hat{x}_k, \delta^h). \end{aligned}$$

where $\hat{x}(t)$, respectively $\hat{x}_k$, is to be found as a solution of:

$$\begin{aligned} \hat{x}(t) &\in \mathcal{X}(t), \quad y(s) = h(X^{\delta^s}(\hat{x}(t), t, s), s, \delta^m(s)) \\ \forall s &\in]t - T, t], \end{aligned}$$

respectively

$$\begin{aligned} \hat{x}_k &\in \mathcal{X}_k, \quad y_l = h_l(X_l^{\delta^s}(\hat{x}_k, k), \delta_l^m) \\ \forall l &\in \{k - K, \dots, k\} \end{aligned}$$

and where the time functions δ^s, δ^m and δ^h must agree with the a priori (deterministic/stochastic) information or minimized in some way.

In this statement T , respectively K , quantify the time window length or memory length during which we record the measurement. The accumulation with time of measurements, together with the model equations (1) to (3) and the assumptions on ($\delta^s, \delta^m, \delta^h$), gives a redundancy of data compared with the number of unknowns that the hidden variables are. This is why it may be possible to solve this observation problem.

To simplify the following presentation, we restrict our attention on the case where the hidden variables are actually the full model state, i.e.,

$$z = \eta(x) = x.$$

When z differs from x , observers are called functional observers.

Set Valued and Conditional Probability Valued Observers

Conceptually the answer to this problem is easy at least when the memory increases with time ($\dot{T}(t) = 1$ resp. $K_{k+1} = K_k + 1$) leading to an infinite non-fading memory. It consists in starting from all what the a priori information makes possible and to eliminate what is not consistent with the a posteriori information. In the set valued observer setting, in the discrete time case, this gives the following observer. To ease its reading, we underline the data given by the a priori information. It requires the introduction of two sets ξ_k and $\xi_{k|k-1}$ which are updated at each time k when a new measurement y_k is made available. ξ_k is the set which x_k is guaranteed to belong to at time k , knowing all the measurements up to time k , and $\xi_{k|k-1}$ is the same but with measurements known up to time $k - 1$.

Set valued observer:

Initialization:

$$\xi_0 = \underline{X}_0$$

At each time k :

prediction (flowing)

$$\xi_{k|k-1} = \underline{f}_{k-1}(\xi_{k-1}, \underline{\Delta}_{k-1}^s)$$

restriction (consistency)

$$\xi_k = \left\{ x \in \left(\xi_{k|k-1} \cap \underline{X}_k \right) : y_k \in \underline{h}_k(x, \underline{\Delta}_k^m) \right\}$$

estimation

$$\widehat{x}_k \in \xi_k$$

A key feature here is that *this observer has a state ξ_k – a set – and is a dynamical system in the form:*

$$\xi_{k+1} = \varphi_k(\xi_k, y_k), \quad \widehat{x}_k \in \xi_k$$

with y as input and $\widehat{x}$ as output which is not single valued. Important also, the initial condition of the state ξ is given by the a priori information.

In the stochastic setting, following the Bayesian paradigm, the observer has the same structure but with the state ξ_k being a conditional probability. See (Jazwinski 2007, Theorem 6.4) or (Candy 2009, Table 2.1). In that setting too the observer is not a single state; it is the (a posteriori) conditional probability of the random variable x_k given the a priori information and the sequence of measurements $l \in \{k - K, \dots, k\} \mapsto y_l$.

Comments

Implementation: For the time being, except for very specific cases (Kalman filter, ...), the set valued and the conditional probability valued observers remain conceptual since we do not know how to manipulate numerically sets and probability laws. Their implementation requires approximations. For instance, see Milanese et al. (1996) and Witsenhausen (1966) for the set case and (Arulampalam et al. 2002); (Bucy and Joseph 1987); (Candy 2009), and (Jazwinski 2007) for the conditional probability case.

Need of finite or infinite but fading memory:

In these observers, model states x which are consistent with the a priori information but do not agree with the a posteriori information are eliminated (set intersection or probability product). But once a point is eliminated, this is for ever. As a consequence if there is, at some time, a misfit between a priori and a posteriori information, it is mistakenly propagated in future times. A way to round this problem is to keep the information memory finite or infinite but fading. In particular, with fixed length memory, consistent points which were disregarded due to measurements which are no more in the memory are reintroduced. This

says also that observers should not be sensitive to their initial condition.

Not single-valued estimate. The observers introduced above realize a lossless data compression with extracting and preserving all what concerns the hidden variables in the redundant data given by a priori and a posteriori information. But this “lossless compression” answer is not single valued (set valued or conditional probability valued) as a result of taking uncertainties into account. Actually, to get a single valued answer, *the observation problem must be complemented by making precise for what the estimation is made.* For instance, we may want to select the most likely or the average or more generally some cost-minimizing estimate $\hat{x}$ among all the possible ones given by ξ . In this way we obtain an observer giving a single-valued estimate:

$$\xi_{k+1} = \varphi_k(\xi_k, y_k), \quad \hat{x}_k = \tau_k(\xi_k)$$

respectively

$$\begin{aligned} \dot{\xi}(t) &= \varphi(\xi(t), y(t), t), \\ \hat{x}(t) &= \tau(\xi(t), t) \end{aligned} \quad (6)$$

But then, in general, we lose information and in particular we have no idea on the confidence level this estimate has. Also, since the function τ , at least, encodes for what the estimate $\hat{x}$ is used, for different uses, different functions τ may be needed.

An Optimization Approach

A shortcut to obtain directly an observer giving a single-valued estimate is to design it by trading off among a priori and a posteriori information (Cox 1964, pages 7–10), Alamir (2007),...). For example, in the continuous time case, we can select the estimate $\hat{x}(t)$ among the minimizers (in x) of:

$$C(\{s \mapsto \delta^s(s)\}, x, t) = \int_{-\infty}^t C(\delta^s(s), y(s), X^{\delta^s}(x, t, s), s) ds$$

where $X^{\delta^s}(x, t, s)$ is still the notation for a solution to (1) and $\{s \mapsto \delta^s(s)\}$, representing the unmodeled effect on the dynamics, is among the arguments for the minimization. The infinitesimal cost C is chosen to take nonnegative values and be such that $C(0, h(x, s), x, s)$ is zero. For instance, it can be:

$$C(\delta^s, y, x, s) = \|\delta^s\|_x^2 + d_y(y, h(x, s))^2$$

where $\|\cdot\|_x$ is a norm at the point x and d_y is a distance in the measurement space. In the same spirit, instead of optimization, a minimax approach can be followed. See, for instance, Bertsekas and Rhodes (1971), Başar (1995, Chapter 7), and Willems (2004).

With x fixed, the minimization of C is an infinite horizon optimal control problem in reverse time. Solving on line this problem is extremely difficult and again approximations are needed. We do not go on with this approach, but we remark that, under extra assumptions, the observer we obtain following this approach can also be implemented in the form of a dynamical system (6) but with the specificity that *the estimate $\hat{x}$ is part of the observer state ξ and its dynamics are a copy of the undisturbed model with a correction term which is zero when the estimated state reproduce the measurement.* Namely, we get:

$$\begin{aligned} \dot{\hat{x}}(t) &= f(\hat{x}(t), t, 0) + E(\{\sigma \mapsto y(\sigma)\}, \\ &\quad \hat{x}(t), y(t), t) \end{aligned}$$

where E is zero when $h(\hat{x}(t), t) = y(t)$. But, as opposed to what we saw in the previous section, the initial condition for the part $\hat{x}$ of the observer state is unknown. Hence we encounter again the need for the observer to forget its initial condition.

Convergent Observers

We have mentioned that often an observer can be implemented as a dynamical system, but without

knowing necessarily how to initialize it. Also approximation is involved both in its design and its implementation. So, at least when it gives a single valued estimate, we are facing the problem of convergence of this estimate to the “true” value, at least when there is no uncertainties. We concentrate now our attention on the study of this convergence, but, to simplify, in the continuous time case only.

Let the model and observer dynamics be:

$$\dot{x}(t) = f(x(t), t), \quad y(t) = h(x(t), t) \quad (7)$$

$$\dot{\xi} = \varphi(\xi(t), y(t), t), \quad \hat{x}(t) = \tau(\xi(t), y(t), t) \quad (8)$$

with the observer state ξ of finite dimension m . We denote by $(X(x, t, s), \Xi((x, \xi), t, s))$ a solution of (7)–(8).

Since we are dealing with convergence, the focus is on what is going on when the time becomes very large and in particular on the set Ω of model states which are accumulation points of some solution. Specifically we are interested in the stability properties of the set:

$$\mathfrak{Z}(t) = \left\{ (x, \xi) : x \in \Omega \text{ \& } x = \tau(\xi, h(x, t), t) \right\}$$

which is contained in the zero estimation error set associated with the given model-observer pair.

Definition 1 (Convergent observer) We say the observer (8) is convergent if, for each t , there exists a set $\mathfrak{Z}_a(t) \subset \mathfrak{Z}(t)$, such that, on the domain of existence of the solution, a distance between the point $(X(x, t, s), \Xi((x, \xi), t, s))$ and the set $\mathfrak{Z}_a(t)$ is upperbounded by a real function $s \mapsto \beta_{x, \xi, t}^c(s)$, maybe dependent on (x, ξ, t) , with nonnegative values, strictly decreasing and going to zero as s goes to infinity.

Necessary Conditions for Observer Convergence

No Restriction on τ

It is possible to prove that, *if the observer is convergent then,*

Necessity of detectability: When h and τ are uniformly continuous in x and ξ , respectively, the estimate $\hat{x}$ does converge to the model state x . In this case, two solutions of the model (7) which produce the same measurement must converge to each other. This is an asymptotic distinguishability property called detectability. If we are interested, not only in the asymptotic behavior but also in the transient (as for output feedback), a property stronger than detectability is needed. In particular instantaneous distinguishability (see section “[Observers Based on Instantaneous Distinguishability](#)”) is necessary if we want to be able to impose the decay rate of the function $\beta_{x, \xi, t}^c$.

Necessity of $m \geq n - p$: For each t , there exists a subset $X_a(t)$ of Ω , supposed to collect the model states which can be asymptotically estimated, and such that we can associate, to each of its point x , a set $\tau^i(x, t)$ allowing us to redefine the set $\mathfrak{Z}_a(t)$ as:

$$\mathfrak{Z}_a(t) = \left\{ (x, \xi) : x \in X_a(t) \text{ \& } \xi \in \tau^i(x, t) \right\}.$$

This implies that, for each t and each x in $X_a(t)$, there is a point ξ satisfying:

$$x = \tau(\xi, h(x, t), t). \quad (9)$$

This is a surjectivity property of the function τ but of a special kind since $h(x, t)$ is an argument of τ . We say that, for each t , *the function τ is surjective to $X_a(t)$ given h* . In a “generic” situation, this property requires the dimension m of the observer state ξ to be larger or equal to the dimension n of the model state x minus the dimension p of the measurement y .

τ Is Injective Given h

We consider now the case where the observer has been designed with a function τ which is injective given h , namely, we have the following implication, when x is in $X_a(t)$:

$$\left[\begin{array}{l} \tau(\xi_1, h(x, t), t) = \tau(\xi_2, h(x, t), t) \quad \& \\ \xi_1 \in \tau^i(x, t) \end{array} \right] \implies \xi_1 = \xi_2.$$

In a “generic” situation, this property, together with the surjectivity given h , implies that the

dimension m of the observer state ξ should be between $n - p$ and n .

If a convergent observer has a such a function τ , then $(x, t) \mapsto \tau^i(x, t)$, which is (of course) a (single valued) function, admits a Lie derivative $L_f \tau^i$ satisfying:

$$\begin{aligned} L_f \tau^i(x, t) &= \lim_{dt \rightarrow 0} \frac{\tau^i(X(x, t, t + dt), t + dt) - \tau^i(x, t)}{dt}, \\ &= \varphi(\tau^i(x, t), h(x, t), t) \quad \forall x \in \mathcal{X}_a(t). \end{aligned} \quad (10)$$

This says (very approximatively) that φ is nothing but the image of the vector field f , under the change of coordinates $(x, t) \mapsto (\tau^i(x, t), t)$ but again all this given h . As partly obtained in the optimization approach, the observer dynamics are then a copy of the model dynamics with maybe a correction term which is zero when the estimated state reproduce the measurement.

If moreover the functions h and τ are uniformly continuous in x and ξ , respectively, then, given ξ_1 and ξ_2 , a distance between $\Xi((x, \xi_1), t, s)$ and $\Xi((x, \xi_2), t, s)$ goes to zero as s goes to infinity. This property is related to what was called extreme stability (see Yoshizawa (1966)) in the 1950s and 1960s and is called incremental stability today (see Angeli (2002)). It holds when, with denoting by $\Xi^y(\xi, t, s)$ the solution at time s of the observer dynamics:

$$\dot{\xi}(t) = \varphi(\xi(t), y(t), t)$$

going through ξ at time t and under the action of y , the flow $\xi \mapsto \Xi^y(\xi, t, s)$ is a strict contraction (See Jouffroy (2005) for a bibliography on contraction) for each $s > t$ or, at least, if a distance between any two solutions $\Xi^y(\xi_1, t, s)$ and $\Xi^y(\xi_2, t, s)$, with the same input y , converges to 0.

Sufficient Conditions

Knowing now how a convergent observer should look like, we move to a quick description of some such observers.

Observers Based on Contraction

Since the flow generated by the observer should be a contraction, we may start its design by picking the function φ as:

$$\dot{\xi}(t) = \varphi(\xi(t), y(t), t) = A \xi(t) + B(y(t), t)$$

where A , not related to f , is a matrix whose eigen values have strictly negative real part. Under weak restriction, there exists a function τ^i satisfying (10), namely:

$$L_f \tau^i(x, t) = A \tau^i(x, t) + B(h(x, t), t). \quad (11)$$

To obtain a convergent observer, it is then sufficient that there exists a (uniformly continuous) function τ satisfying:

$$x = \tau(\tau^i(x, t), h(x, t), t)$$

For this to be possible, the function τ^i should be injective given h . This injectivity holds when the observer state has dimension $m \geq 2(n + 1)$, the model is distinguishable, and provided the eigen values of A have a sufficiently negative real part and are not in a set of zero Lebesgue measure.

Unfortunately, we are facing again a possible difficulty in the implementation since an expression for a function τ^i satisfying (11) is needed and the function $\tau : (\xi, y, t) \mapsto \hat{x}(t)$ is known implicitly only as:

$$\xi = \tau^i(\hat{x}(t), t).$$

See Andrieu and Praly (2006), Luenberger (1964), and Shoshitaishvili (1990).

Observers Based on Instantaneous

Distinguishability

Instantaneous distinguishability means that we can distinguish as quickly as we want two model states by looking at the paths of the measurements they generate. A sufficient condition to have this property can be obtained by looking at the Taylor expansion in s of $h(X(x, t, s), s)$. Indeed, we have:

$$h(X(x, t, s), s) = \sum_{i=0}^{m-1} h_i(x, t) \frac{(s-t)^i}{i!} + o((s-t)^{m-1})$$

where h_i is a function obtained recursively as:

$$\begin{aligned} h_0(x, t) &= h(x, t) \quad h_{i+1}(x, t) = \overline{\dot{h}_i(x, t)} \\ &= \frac{\partial h_i}{\partial x}(x, t) f(x, t) + \frac{\partial h_i}{\partial t}(x, t). \end{aligned}$$

If there exists an integer m such that, in some uniform way with respect to t , the function

$$x \mapsto H_m(x, t) = (h_0(x, t), \dots, h_{m-1}(x, t))$$

is injective, then we do have instantaneous distinguishability. We say the system is differentially observable of order m when this injectivity property holds. When a system has such a property, the model state space has a very specific structure as discussed in Isidori (1995, Section 1.9). It means that we can reconstruct x from the knowledge of y and its $m-1$ first time derivatives, i.e., there exists a function Φ such that we have:

$$x = \Phi(H_m(x, t), t).$$

This way, we are left with estimating the derivatives of y . This can be done as follows. With the notation $\eta_i = h_{i-1}(x, t)$, we obtain:

$$\dot{\eta}(t) = F \eta + G h_m(\Phi(\eta(t), t), t)$$

where

$$F \eta = (\eta_2, \dots, \eta_m, 0), \quad G = (0, \dots, 0, 1).$$

When the last term on the right-hand side is Lipschitz, we can find a convergent observer in the form:

$$\begin{aligned} \dot{\hat{\xi}}(t) &= F \hat{\xi}(t) + G h_m(\hat{x}(t), t) \\ &\quad + K(y(t) - \xi_1(t)), \quad \hat{x}(t) = \tau(\hat{\xi}(t), t), \end{aligned}$$

with $\hat{\xi}$ being actually an estimation of η and where K is a constant matrix and τ is a modified version of Φ keeping the estimated state in its a priori given set $\mathcal{X}(t)$.

This is the high-gain observer paradigm. See Gauthier and Kupka (2001) and Tornambe (1988). The implementation difficulty is in the function $\hat{\Phi}$, not to mention sensitivity to measurement uncertainty.

Observers With τ Bijective Given h

Case Where τ Is the Identity Function

A convergent observer whose function τ is the identity has the following form:

$$\begin{aligned} \dot{\hat{\xi}} &= f(\hat{\xi}, t) + E(\{\sigma \mapsto y(\sigma)\}, \hat{\xi}(t), y(t), t), \\ \hat{x}(t) &= \hat{\xi}(t). \end{aligned} \tag{12}$$

The only piece remaining to be designed is the correction term E . It has to ensure convergence and may be also other properties like symmetry preserving (see Bonnabel et al. 2008).

For this design, a first step is to exhibit some specific properties of the vector field f by writing it in some appropriate coordinates. For example, there may exist coordinates such that the expression of f takes the form $\hat{f}(x(t), h(x, t), t)$ and the corresponding observer (12) is such that there exists a positive definite matrix P for which the function $s \mapsto (X(x, t, d) - \hat{X}((x, \hat{x}), t, s))' P (X(x, t, d) - \hat{X}((x, \hat{x}), t, s))$ is strictly decaying (if not zero). A necessary condition for this to be possible is that f is

monotonic tangentially to the level sets of the function h , i.e., for all (x, y, v, t) satisfying $y = h(x, t)$ and $\frac{\partial h}{\partial x}(x, t)v = 0$, we have:

$$v^T P \frac{\partial f}{\partial x}(x, y, t) v \leq 0. \quad (13)$$

This is another way of expressing a detectability condition. This expression is coordinate dependent, hence the importance of choosing the coordinates properly.

When this condition is strict and uniform in t , it is sufficient to get a locally convergent observer and even a nonlocal one when h is linear in x , i.e., $h(x, t) = H(t)x$, again a coordinate-dependent condition. In this latter case the observer takes the form:

$$\begin{aligned} \dot{\xi}(t) &= f(\xi(t), y(t), t) + \ell(\xi(t)) P^{-1} H(t)^T \\ &\quad [y(t) - H(t)\xi(t)], \quad \hat{x}(t) = \xi(t), \end{aligned}$$

where ℓ is a real function to be chosen with sufficiently large values. If (13) is strict and uniform and holds for all v , the correction term is not needed.

There are many other results of this type, exploiting one or the other specificity of the dependence on x of the function f – monotonicity, convexity, See Fan and Arcak (2003), Krener and Isidori (1983), Respondek et al. (2004) and Sanfelice (2012), ...

Case Where $(x, t) \mapsto (\tau^i(x, t), h(x, t), t)$ Is a Diffeomorphism

At each time t we know already that the model state x we want to estimate satisfies $y(t) = h(x, t)$. So, as remarked in Luenberger (1964), when $(h(x, t), t)$ can be used as part of coordinates for (x, t) , we need to estimate the remaining part only. This can be done if we find a function τ^i , whose values are $n - p$ dimensional, such that $(x, t) \mapsto (y, \eta, t) = (h(x, t), \tau^i(x, t), t)$ is a diffeomorphism and the flow $\eta \mapsto \eta^y(\eta, t, s)$ generated by

$$\begin{aligned} \dot{\eta}(t) &= \frac{\partial \tau^i}{\partial x}(x(t), t) f(x(t), t) + \frac{\partial \tau^i}{\partial t}(x(t), t), \\ &= \varphi(\eta(t), y(t), t) \end{aligned}$$

is a strict contraction for all $s > t$. Indeed in this case the observer dynamics can be chosen as:

$$\dot{\xi}(t) = \varphi(\xi(t), y(t), t)$$

and the estimate $\hat{x}(t)$ is obtained as solution of:

$$\tau^i(\hat{x}(t), t) = \xi(t), \quad h(\hat{x}(t), t) = y(t).$$

This is the reduced order observer paradigm. See, for instance, Besançon (2000, Proposition 3.2), and Carnevale et al. (2008), and Luenberger (1964, Theorem 4).

Abstract

Observers are dynamical systems which process the input and output signals of a given dynamical system and deliver an online estimate of the internal state of the system which asymptotically converges to the exact value of the state. For linear, finite-dimensional, time-invariant systems, observers can be designed provided a weak observability property, known as detectability, holds.

State observer · Reduced order observer · Detectability

Introduction

Consider a linear, finite-dimensional, time-invariant system described by equations of the form

$$\begin{aligned}\sigma x &= Ax + Bu, \\ y &= Cx + Du,\end{aligned}\tag{1}$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^p$, $t \in T \subset \mathbb{R}$, and A , B , C , and D matrices of appropriate dimensions and with constant entries and the problem of estimating its state from

measurements of the input and output signals. In Eq. (1) $\sigma x(t)$ stands for $\dot{x}(t)$, if the system is continuous-time, and for $x(t+1)$, if the system is discrete-time. In addition, if the system is continuous-time, then $T \in \mathbb{R}^+$, i.e., the set of nonnegative real numbers, whereas if the system is discrete-time, then $T \in \mathbb{Z}^+$, i.e., the set of nonnegative integers.

We are interested in determining an online estimate $x_e(t) \in \mathbb{R}^n$, i.e., the estimate at time t has to be a function of the available information (input and output) at the same time instant. This implies that the estimate is generated by means of a device (known as a *filter*) processing the current input and output of the system and generating a state estimate. The filter may be instantaneous, i.e., the estimate is generated instantaneously by processing the available information. In this case we have a static filter. Alternatively, the state estimate can be generated processing the available information through a dynamical device. In this case we have a dynamic filter.

Assume, for simplicity, that $D = 0$. This assumption is without loss of generality: if $y = Cx + Du$ and u are measured, then also $\tilde{y} = Cx$ is measured. Assume, in addition, that the filter which generates the online estimate is linear, finite-dimensional, and time-invariant. Then we may have the following two configurations.

- *Static filter.* The state estimate is generated via the relation

$$x_e = My + Nu, \quad (2)$$

with M and N constant matrices of appropriate dimensions. The resulting interconnected system is described by the equations

$$\begin{aligned} \sigma x &= Ax + Bu, \\ x_e &= MCx + Nu. \end{aligned} \quad (3)$$

- *Dynamic filter.* The state estimate is generated by the system

$$\begin{aligned} \sigma \xi &= F\xi + Ly + Hu, \\ x_e &= M\xi + Ny + Pu, \end{aligned} \quad (4)$$

with F, L, H, M, N and P constant matrices of appropriate dimensions. The resulting interconnected system is described by the equations

$$\begin{aligned} \sigma x &= Ax + Bu, \\ \sigma \xi &= F\xi + LCx + Hu, \\ x_e &= M\xi + NCx + Pu. \end{aligned} \quad (5)$$

In what follows, we study in detail the dynamic filter configuration. This is mainly due to the fact that this configuration allows solving most estimation problems for linear systems. Moreover, while the use of a static filter is very appealing, it provides a useful alternative only in very specific situations.

State Observer

A state observer is a filter that allows to estimate, asymptotically or in finite time, the state of a system from measurements of the input and output signals.

The simplest possible observer can be constructed considering a copy of the system, the state of which has to be estimated. This means that a candidate observer for system (1) is given by

$$\begin{aligned} \sigma \xi &= A\xi + Bu, \\ x_e &= \xi. \end{aligned} \quad (6)$$

To assess the properties of this candidate state observer, let $e = x - x_e$ be the estimation error, and note that $\sigma e = Ae$. As a result, if $e(0) = 0$ then $e(t) = 0$ for all t and for any input signal u . However, if $e(0) \neq 0$, then, for any input signal u , $e(t)$ is bounded only if the system (1) is stable and converges to zero only if the system (1) is asymptotically stable. If these conditions do not hold, the estimation error is not bounded, and system (6) does not qualify as a state observer for system (1). The intrinsic limitation of the observer (6) is that it does not use all the available information, i.e., it does not use the knowledge of the output signal y . This observer is therefore an open-loop observer.

To exploit the knowledge of y we modify the observer (6) adding a term which depends upon the available information on the estimation error, which is given by $y_e = Cx_e - y$. This modification yields a candidate state observer described by

$$\begin{aligned}\sigma \xi &= A\xi + Bu + Ly_e, \\ x_e &= \xi.\end{aligned}\quad (7)$$

To assess the properties of this candidate state observer note that $e = x - x_e$ is such that

$$\sigma e = (A + LC)e. \quad (8)$$

The matrix L (known as *output injection gain*) can be used to shape the dynamics of the estimation error. In particular, we may select L to assign the characteristic polynomial $p(s)$ of $A + LC$. To this end, note that (the notation M' is used to denote the transpose of the matrix M)

$$p(s) = \det(sI - (A + LC)) = \det(sI - (A' + C'L')).$$

Hence, there is a matrix L which arbitrarily assigns the characteristic polynomial of $A + LC$ if and only if the system

$$\sigma \xi = A'\xi + C'v$$

is reachable or, equivalently, if and only if the system (1) is observable.

We summarize the above discussion with two formal statements.

Proposition 1 *Consider system (1) and suppose the system is observable. Let $p(s)$ be a monic polynomial of degree n . Then there is a matrix L such that the characteristic polynomial of $A + LC$ is equal to $p(s)$.*

Note that for single-output systems, the matrix L assigning the characteristic polynomial of $A + LC$ is unique.

Proposition 2 *System (1) is observable if and only if it is possible to arbitrarily assign the eigenvalues of $A + LC$.*

Detectability

The main goal of a state observer is to provide an online estimate of the state of a system. This goal may be achieved, as discussed in the previous section, if the system is observable. However, observability is not necessary to achieve this goal: in fact the unobservable modes (that is the eigenvalues of the unobservable part of the system) are not modified by the output injection gain. This implies that there exists a matrix L such that system (8) is asymptotically stable if and only if the unobservable modes of system (1) have negative real part, in the case of continuous-time systems, or have modulus smaller than one, in the case of discrete-time systems. To capture this situation we introduce a new definition.

Definition 1 (Detectability) System (1) is detectable if its unobservable modes have negative real part, in the case of continuous-time systems, or have modulus smaller than one, in the case of discrete-time systems.

Example (Dead-beat observer) Consider a discrete-time system described by equations of the form

$$\begin{aligned}x(t+1) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t),\end{aligned}$$

and the problem of designing a state observer, described by the Eqs. (7), such that, for any initial condition $x(0)$ and for any input u , $e(k) = 0$, for all $k \geq N$, and for some $N > 0$. A state observer achieving this goal is called a dead-beat state observer. To achieve this goal it is necessary to select L such that $(A + LC)^N = 0$ or, equivalently, such that the matrix $A + LC$ has all eigenvalues equal to 0. Note that $N \leq n$. $\diamond$

Reduced Order Observer

We have shown that, under the hypotheses of observability or detectability, it is possible to design an asymptotic observer of order n for the

system (1). However, this observer is somewhat oversized, i.e., it gives an estimate for the n components of the state vector, without making use of the fact that some of these components can be directly determined from the output function, e.g., if $y = x_1$ there is no need to reconstruct x_1 . It makes sense, therefore, to design a *reduced order observer*, i.e., a device that estimates only the part of the state vector which is not directly attainable from the output. To this end, consider the system (1) with $D = 0$, and assume that the matrix C has p independent rows. This is without loss of generality: in fact this is the case if $\text{rank } C = p$, whereas if $\text{rank } C < p$, it is always possible to eliminate redundant rows from C . Then there exists a matrix Q such that, possibly after reordering the state variables,

$$QC = [I \ C_2].$$

Let

$$v = Qy = QCx = x_1 + C_2x_2,$$

in which $x_1(t) \in \mathbb{R}^p$ and $x_2(t) \in \mathbb{R}^{n-p}$ denote the first p and the last $n - p$ components of x .

Observe that the vector v is measured. From the definition of v we conclude that if v and x_2 are known then x_1 can be easily computed, i.e., there is no need to construct an observer for x_1 .

Define now the new coordinates

$$\begin{bmatrix} \hat{x}_1 \\ \hat{x}_2 \end{bmatrix} = Tx = \begin{bmatrix} I & C_2 \\ 0 & I \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

and note that, by construction, $v = Qy = \hat{x}_1$. In the new coordinates the system, with output v , is described by equations of the form

$$\begin{aligned} \sigma \hat{x}_1 &= \tilde{A}_{11}\hat{x}_1 + \tilde{A}_{12}\hat{x}_2 + \tilde{B}_1u, \\ \sigma \hat{x}_2 &= \tilde{A}_{21}\hat{x}_1 + \tilde{A}_{22}\hat{x}_2 + \tilde{B}_2u, \\ v &= \hat{x}_1. \end{aligned}$$

To construct an observer for $\hat{x}_2$ consider the system

$$\sigma \xi = F\xi + Hv + Gu,$$

with state ξ , driven by u and v , and with output

$$w = \xi + Lv.$$

The idea is to select the matrices F , H , G , and L in such a way that w is an estimate for $\hat{x}_2$. Let $w - \hat{x}_2$ be the observation error. Then

$$\begin{aligned} \sigma w - \sigma \hat{x}_2 &= F\xi + Hv + Gu + L \left[\tilde{A}_{11}\hat{x}_1 + \tilde{A}_{12}\hat{x}_2 + \tilde{B}_1u \right] - \left[\tilde{A}_{21}\hat{x}_1 + \tilde{A}_{22}\hat{x}_2 + \tilde{B}_2u \right] \\ &= F\xi + \left(H + L\tilde{A}_{11} - \tilde{A}_{12} \right) \hat{x}_1 + \left[L\tilde{A}_{12} - \tilde{A}_{22} \right] \hat{x}_2 + \left[G + L\tilde{B}_1 - \tilde{B}_2 \right] u. \end{aligned} \quad (9)$$

To have convergence of the estimation error to zero, regardless of the initial conditions and of the input signal, we must have

$$\sigma(w - \hat{x}_2) = F(w - \hat{x}_2) \quad (10)$$

and F must have all eigenvalues with negative real part, in the case of continuous-time systems, or with modulus smaller than one, in the case of discrete-time systems. Comparing Eqs. (9) and

(10), we obtain that the matrices F , H , G , and L must be such that

$$\begin{aligned} L\tilde{A}_{12} - \tilde{A}_{22} &= -F, \\ H + L\tilde{A}_{11} - \tilde{A}_{21} &= FL, \\ G + L\tilde{B}_1 - \tilde{B}_2 &= 0. \end{aligned} \quad (11)$$

We now show how the Eq. (11) can be solved and how the stability condition on F can be

enforced. Detectability of the system implies that the (reduced system) $\sigma \tilde{\xi} = \tilde{A}_{22} \tilde{\xi}$ with output $\tilde{y} = \tilde{A}_{12} \tilde{\xi}$ is detectable. As a result, there exists a matrix L such that the matrix

$$F = \tilde{A}_{22} - L \tilde{A}_{12}$$

has all eigenvalues with negative real part, in the case of continuous-time systems, or with modulus smaller than one, in the case of discrete-time systems. Then the remaining equations are solved by

$$\begin{aligned} H &= FL - L \tilde{A}_{11} + \tilde{A}_{21}, \\ G &= -L \tilde{B}_1 + \tilde{B}_2. \end{aligned}$$

Finally, from $\hat{x}_1 = v$ and the estimate w of $\hat{x}_2$, we build an estimate x_e of the state x inverting the transformation T , i.e.,

$$\begin{bmatrix} x_{1e} \\ x_{2e} \end{bmatrix} = \begin{bmatrix} I & -C_2 \\ 0 & I \end{bmatrix} \begin{bmatrix} v \\ w \end{bmatrix}.$$

Summary and Future Directions

The problem of online estimating the state of a linear system from input and output measurements can be solved provided a weak observability condition holds. The problem addressed in this entry is the simplest possible estimation problem: the underlying system is linear, and all variables are exactly measured. Observers for nonlinear systems and in the presence of signals corrupted by noise can also be designed exploiting some of the basic ingredients, such as the notions of error system and of output injection, discussed in this entry.

Opacity of Discrete Event Systems

Christoforos N. Hadjicostis
Department of Electrical and Computer Engineering, University of Cyprus, Nicosia, Cyprus

Abstract

We discuss ways to formulate, analyze, verify, and enforce different notions of opacity in discrete event systems. Opacity captures a class

of information flow properties that are important for security/privacy analysis and focus on the type of inferences that a passive intruder can make regarding a subset of the behavior of the system, called the secret behavior. The secret behavior represents critical aspects of the given system that need to be kept hidden from the passive intruder, which is modeled as an external observer with (partial) knowledge of the system model and access to certain observed system behavior.

Keywords

Discrete event systems · Opacity · Privacy · Security · Finite automata · Petri nets · Verification

Introduction

Opacity is an important security/privacy notion that has emerged as a major research direction in discrete event systems (DES) in the last two decades. Given an underlying DES, opacity aims to characterize the type of inferences that a passive observer can make regarding a subset of the behavior of the system that is considered critical and is referred to as the *secret behavior*. The secret behavior models activity in the system that reveals important details about the operation of the system and needs to be kept hidden, whereas the passive observer captures an external entity (intruder) that cannot issue commands to influence the operation of the system but can nevertheless observe (perhaps partially) activity in the system. By combining observations resulting from activity in the system together with its knowledge of the system model (e.g., partial knowledge of the transition structure and the initial state of the system), this intruder essentially acts as an external observer that tries to infer whether the system has (likely or certainly, depending on the notion of opacity that is under consideration) executed activity within the secret behavior. Many related privacy/security notions, such as transitive noninterference and anonymity, can be formulated as instances of opacity.

One of the reasons that opacity has emerged at the forefront of DES research is the ever-increasing dependence of many technological systems and applications on shared cyberinfrastructure (ranging from defense and banking to health care and power distribution systems), which has prompted increased attention on various aspects of privacy and security. As an example, consider a shopping district where a security guard patrols the area in order to monitor the status of different stores. This can be modeled as a transition system (e.g., a finite automaton) with states corresponding to the different locations (stores) and with transitions corresponding to the pathways (routes) that are available between locations. Locations and/or pathways may be equipped with sensors that indicate when a location/pathway (or a subset of locations/pathways) is used. A typical opacity problem may require that the intruder (external observer) cannot identify that the guard resides outside a subset of strategic locations (e.g., banks or stores that sell expensive goods), which would indicate a convenient time for the intruder to attempt to infiltrate a strategic location.

Not surprisingly, the range of applications has also prompted many variations of opacity in DES. *Strong* notions of opacity typically require that the intruder will *never* be able to establish with *certainty* that secret behavior has occurred in the system, i.e., regardless of the underlying activity that occurs in the system, the observations that are generated can always be explained with behavior that is non-secret (implying that the external observer cannot be absolutely certain about the presence of secret behavior). Relaxations of strong notions of opacity have been pursued in two distinct directions. *Weak* opacity only requires that, for *some* behavior in the system, the intruder will never be able to establish with *certainty* that secret behavior has occurred in the system (but for other behavior, this may not necessarily be true, indicating that perhaps one should carefully confine the system behavior to ensure opacity). In stochastic systems, where activity occurs with certain probability, researchers have also developed *probabilistic* notions of opacity.

Depending on the formulation, probabilistic notions of opacity aim at either (i) analyzing the prior probability of system behavior for which the intruder may be able to infer that secret behavior has occurred with certainty (i.e., analyzing the prior probability with which strong opacity will hold) or (ii) analyzing for each scenario the posterior probability (confidence) with which the intruder might be able to conclude that secret behavior has occurred (e.g., even though the intruder may not be certain about the occurrence of secret behavior based on the observations, it may be able to infer that secret behavior has occurred with high probability).

Unlike notions of fault diagnosis discussed in ▶ “[Diagnosis of Discrete Event Systems](#)”, opacity is concerned with the hiding of information rather than the revelation of information. In the fault diagnosis setting, we are given a system with certain special (typically unobservable) events, called faults, and the goal is to determine the occurrence of these fault events. In such setting, *diagnosability* is a property that holds for the system if, under all possible system behavior that includes at least one fault event, the external observer (called diagnoser in this case) can determine (at least after a finite number of observations, i.e., with some finite delay) that the fault has occurred. To compare opacity with diagnosability, we can take the system’s secret behavior to be behavior that includes the occurrence of one or more faults. In such case, opacity would hold in the given system if under all system behavior (and also behavior that includes the fault), the external observer can never be certain that a fault has occurred. It should be clear that there is an inverse relationship between opacity and diagnosability for a given system; however, the two notions are not exact opposites. If secret behavior is taken to be behavior that includes the occurrence of one or more faults, the system cannot be opaque if it is diagnosable; however, a system that is not opaque can be diagnosable or non-diagnosable. Some discussions on the connections between diagnosability and opacity can be found in Lafortune et al. (2018).

In our opacity discussions in this article, we focus primarily on DES that can be modeled as

finite automata and only briefly describe extensions to other types of discrete event systems (in particular, probabilistic finite automata and Petri nets). The focus on finite automata allows us to concisely describe various notions of opacity, though it might be constraining in terms of some engineering applications.

Opacity in Finite Automata

Notions of opacity have been studied quite extensively in non-deterministic finite automata (NFAs) under partial observation. In this section, we describe some of the basic opacity formulations that have been investigated in this context, as well as ways to verify that they hold. Opacity notions for NFAs can be classified in two categories, depending on how the secret behavior of the NFA is described. *State-based* notions of opacity define the secret behavior with respect to a given subset of secret states S , whereas *language-based* notions of opacity define the secret behavior as a sublanguage L_S of the given NFA (i.e., a subset of finite-length sequences of events that can be generated by the NFA).

Notation and Preliminaries

This section briefly describes some notation and preliminaries, for which one can also refer to “Modeling by Cassandra”.

Let Σ be an alphabet (set of events) and denote by Σ^* the set of all finite-length strings of elements of Σ (sequences of events), including the empty string ε . A language $L \subseteq \Sigma^*$ is a subset of finite-length strings in Σ^* , i.e., sequences of a certain number of events with the convention that the first event appears on the left. Given strings $s, t \in \Sigma^*$, the string st denotes the concatenation of s and t , i.e., the sequence of events captured by s followed by the sequence of events captured by t . For any set Q , we use $|Q|$ to denote the cardinality (number of elements) of Q .

Definition 1 (Non-deterministic Finite Automaton (NFA)) A non-deterministic finite automaton is captured by $G = (X, \Sigma, \delta, X_0)$, where $X = \{x_1, x_2, \dots, x_N\}$ is the set of states,

$\Sigma = \{\sigma_1, \sigma_2, \dots, \sigma_K\}$ is the set of events, $\delta : X \times \Sigma \rightarrow 2^X$ is the non-deterministic state transition function, and $X_0 \subseteq X$ is the set of possible initial states.

Remark 1 An NFA $G = (X, \Sigma, \delta, X_0)$ is called *deterministic* if for all $x \in X$ and all $\sigma \in \Sigma$, we have $|\delta(x, \sigma)| \leq 1$. In such case, we often write $\delta(x, \sigma) = x'$ if $\delta(x, \sigma) = \{x'\}$ or say that $\delta(x, \sigma)$ is undefined if $\delta(x, \sigma) = \emptyset$.

For a subset of states $Q \subseteq X$ and $\sigma \in \Sigma$, we define $\delta(Q, \sigma) = \cup_{q \in Q} \delta(q, \sigma)$; with this notation at hand, the function δ can be extended from the domain $X \times \Sigma$ to the domain $X \times \Sigma^*$ in the routine recursive manner $\delta(x, \sigma s) := \delta(\delta(x, \sigma), s)$ for $x \in X$, $\sigma \in \Sigma$, and $s \in \Sigma^*$ (note that we define $\delta(x, \varepsilon) := \{x\}$). The behavior of G is captured by its language $L(G) := \{s \in \Sigma^* \mid \exists x_0 \in X_0 \text{ such that } \delta(x_0, s) \neq \emptyset\}$. We use $L(G, x)$ to denote the set of all traces that originate from state x of G (so that $L(G) = \bigcup_{x_0 \in X_0} L(G, x_0)$).

A very common way of capturing the capability of the external observer (intruder) is to assume that it can only observe a subset Σ_{obs} ($\Sigma_{obs} \subseteq \Sigma$) of the events. This means that Σ is partitioned into the set of observable events Σ_{obs} and the set of unobservable events $\Sigma_{uo} := \Sigma \setminus \Sigma_{obs}$. The natural projection $P_{\Sigma_{obs}} : \Sigma^* \rightarrow \Sigma_{obs}^*$ can be used to map any trace executed in the system to the sequence of observations associated with it. This projection is defined recursively as $P_{\Sigma_{obs}}(s\sigma) = P_{\Sigma_{obs}}(s)P_{\Sigma_{obs}}(\sigma)$, $s \in \Sigma^*$, $\sigma \in \Sigma$, with

$$P_{\Sigma_{obs}}(\sigma) = \begin{cases} \sigma, & \text{if } \sigma \in \Sigma_{obs}, \\ \varepsilon, & \text{if } \sigma \in \Sigma_{uo} \cup \{\varepsilon\}, \end{cases}$$

where ε represents the empty (observation) trace. In the sequel, the subscript Σ_{obs} in $P_{\Sigma_{obs}}$ will be dropped when it is clear from context.

Current-State Opacity

Perhaps the most common way of defining opacity is in terms of the perceived current state of the system. In particular, given an NFA $G = (X, \Sigma, \delta, X_0)$, a natural projection mapping P with respect to a set of observable events Σ_{obs} , and a set of secret states S ($S \subseteq X$), the system G

is said to be *current-state opaque* if the entrance of the system state to the secret set S remains *opaque* (hidden) to an external observer – at least until the system leaves the set of secret states. Current-state opacity in NFA settings has been shown to be useful in characterizing security requirements in many applications (including encryption using pseudorandom generators and coverage properties in sensor networks Saboori and Hadjicostis 2007, 2011 and Dubreil et al. 2010). Formally, current-state opacity can be defined as follows (Saboori and Hadjicostis 2007).

Definition 2 (Current-State Opacity) Consider an NFA $G = (X, \Sigma, \delta, X_0)$, along with a natural projection map P with respect to the set of observable events Σ_{obs} . We say that G is *current-state opaque* with respect to a set of secret states $S \subseteq X$, if for all $t \in L(G)$ we can find an $s \in L(G)$ such that

$$\delta(X_0, s) \cap S \neq \delta(X_0, t) \text{ and } P(s) = P(t).$$

Remark 2 Note that string s in the above definition could also be t in case $\delta(X_0, t) \cap S \neq \delta(X_0, t)$. Also note that in the above definition we have $\delta(X_0, t) \neq \emptyset$ and $\delta(X_0, s) \neq \emptyset$ (since $t, s \in L(G)$).

The above definition of current-state opacity can be rephrased in terms of the current-state estimates that the external observer reaches following the execution of a sequence of events $t \in L(G)$. More specifically, t will lead to the sequence of observations $P(t)$, and the requirement is that, for all $t \in L(G)$, the set of possible current-state estimates defined as

$$\hat{x}(P(t)) = \{x \in X \mid \exists x_0 \in X_0, \exists s \in L(G, x_0) \text{ s.t. } x \in \delta(x_0, s) \text{ and } P(s) = P(t)\} \quad (1)$$

should not be a subset of the set of secret states S , i.e., $\hat{x}(P(t)) \cap S \neq \hat{x}(P(t))$.

Once the above connection is established, it is not surprising that current-state opacity for a given NFA G can be verified using its corresponding observer automaton. The observer automaton $G_{obs} = (X_{obs}, \Sigma_{obs}, \delta_{obs}, X_{0,obs})$

(see, e.g., the discussion in Cassandras and Lafortune 2009) of the given NFA G is a deterministic finite automaton, where $X_{obs} \subseteq 2^X$ and Σ_{obs} is the set of observable events, that satisfies the following:

1. The initial state satisfies $X_{0,obs} = \{x \in X \mid \exists x_0 \in X_0, \exists t \in \Sigma_{uo}^* \text{ s.t. } x \in \delta(x_0, t)\}$. In other words, $X_{0,obs}$ corresponds to the set of states of G that can be reached from at least one of the initial states in X_0 via zero, one, or more unobservable events; this is also known as the unobservable reach from the set of states X_0 .
2. For $x_{obs} \in X_{obs}$ and $\sigma_o \in \Sigma_{obs}$, the next state transition function δ_{obs} is defined as $x'_{obs} = \delta_{obs}(x_{obs}, \sigma_o)$ where

$$x'_{obs} = \{x' \in X \mid \exists x \in x_{obs}, s \in \Sigma^* \text{ such that } x' \in \delta(x, s) \text{ and } P(s) = \sigma_o\}.$$

[If $x'_{obs} = \delta_{obs}(x_{obs}, \sigma_o)$ is the empty set, we often take $\delta_{obs}(x_{obs}, \sigma_o)$ to be undefined and not include $x'_{obs} = \emptyset$ in X_{obs} .]

The basic property of the observer automaton is that it can be used to obtain an estimate of the set of possible states of the system following any sequence of observations. More specifically, a sequence of events $t \in L(G)$ that occurs in the given system G generates the sequence of observations $P(t) \in \Sigma_{obs}^*$, and the corresponding set of state estimates, defined earlier as $\hat{x}(P(t))$, can be shown to satisfy

$$\hat{x}(P(t)) = \delta_{obs}(X_{0,obs}, P(t)),$$

where the definition of δ_{obs} is extended for strings of observable events (in Σ_{obs}^*) in the routine recursive manner described earlier.

Given that we have constructed the observer G_{obs} , we can verify current-state opacity for NFA G in a straightforward manner (Saboori and Hadjicostis 2007, 2011): if there exists a state x_{obs} of the observer that is nonempty and satisfies $x_{obs} \subseteq S$ (and is accessible from the initial state $X_{0,obs}$), then we know that the system is not

Opacity of Discrete Event Systems, Fig. 1 NFA G (top) and its observer G_{obs} (bottom) considered in Example 1

current-state opaque (and vice versa). Since the construction of the observer is worst-case exponential in the size of the given NFA, this approach for verifying current-state opacity has exponential complexity. It turns out that the verification of current-state opacity is a PSPACE-complete problem (see, e.g., Saboori and Hadjicostis 2011 and Cassez et al. 2012); therefore, it is unlikely that a polynomial algorithm for verifying current-state opacity exists.

Example 1 Consider NFA $G = (X, \Sigma, \delta, X_0)$ at the top of Fig. 1 with states $X = \{1, 2, 3, 4\}$, events $\Sigma = \{a, b, c, d\}$, transition function δ as shown in the figure, and initial states $X_0 = \{1, 2, 3, 4\}$. Assuming that the set of observable events $\Sigma_{obs} = \{a, b, d\}$, the observer of the system is shown at the bottom of Fig. 1. Each of the states of the observer is associated with a subset of X . In particular, the initial state of the observer is $X_{0,obs} = \{1, 2, 3, 4\}$ since initially NFA G could be in any state. From this initial observer state, there are three possible observations: (i) if a is observed the only possible states are states

in the set $\{1, 2, 3\}$ (state 1 can be reached from state 2 via the unobservable event c); (ii) if b is observed, the only possible states are states in the set $\{3, 4\}$ (state 3 can be reached from state 4 via the unobservable event c); and (iii) if d is observed, the only possible states are states in the set $\{1, 2\}$ (again, state 1 can be reached from state 2 via the unobservable event c). The observer construction can be completed by considering all possible observations (a and/or b and/or d) from each observer state.

Having constructed the observer, it is easy to verify current-state opacity with respect to a set of secret states S . For illustration purposes, we consider two different sets of secret states.

1. If $S = \{1, 2\}$, then NFA G is not current-state opaque. This is easy to see from the observer construction: the observer state that is associated with $\{1, 2\}$ is a subset of S and indicates a violation of current-state opacity. For instance, if we observe d (or bd or $bdbd$ or ad , etc.), the external observer will be certain that the system is in one of the secret states in the set $\{1, 2\}$. [Note that a sequence of observations gets generated in response to a sequence of events: for instance, the sequence of events bcd will generate the sequence of observations bd , which leads to a violation of current-state opacity.]
2. If $S = \{1, 3\}$ then NFA G is current-state opaque. This is easy to see from the observer construction as no (non-empty) observer state is associated with a subset of S (thus, a violation of current-state opacity is not possible).

Other State-Based Notions of Opacity

Apart from current-state opacity, many other state-based notions of opacity have been studied. These include current-state anonymity, initial-state opacity, K -step opacity, initial- and final-state opacity, infinite-step opacity, and many others. In all cases, the underlying system is captured by an NFA $G = (X, \Sigma, \delta, X_0)$ under a natural projection map P with respect to the set of observable events Σ_{obs} . The differences pertain to the way opacity violations are captured and the point(s) in time we are interested in. The work

in Wu and Lafortune (2013) has established that many of these notions (as well as language-based opacity which is discussed in the next section) are polynomially reducible from one to another.

In the remainder of this section, we briefly describe current-state anonymity and initial-state opacity.

Current-state anonymity does not involve a specific set of secret states S , but it is concerned with whether the external observer can determine the current state of the system exactly (the motivation in Wu et al. (2014) comes from the desire to maintain privacy when an agent attempts to use location-based services, with the state of the system being associated to the location of the agent). Formally, we have the following definition.

Definition 3 (Current-State Anonymity) Consider an NFA $G = (X, \Sigma, \delta, X_0)$, along with a natural projection map P with respect to the set of observable events Σ_{obs} . We say that current-state anonymity holds for G if for all $x_0 \in X_0$ and all $t \in L(G, x_0)$, the following is true: if $|\delta(x_0, t)| = 1$, then there exist $x'_0 \in X_0$ and $s \in L(G, x'_0)$, such that (i) $\delta(x'_0, s) \cap \delta(x_0, t) \neq \delta(x'_0, s)$ and (ii) $P(s) = P(t)$.

Another way of stating the current-state anonymity requirement is to say that

$$|\hat{x}(P(t))| > 1, \forall t \in L(G),$$

where $\hat{x}(P(t))$ was defined in (1) as the set of current-state estimates following the observation of $P(t)$. Recall that $\hat{x}(P(t))$ can be obtained as the set of states associated with the state of the observer G_{obs} reached via $\delta_{obs}(X_{0,obs}, P(t))$. Thus, one can verify current-state anonymity for a given system G by constructing its observer G_{obs} and checking that each observer state (that is reachable from the initial state) is associated with a set of state estimates of cardinality greater than unity (or zero, if we allow the observer to have a state associated with the empty set). Again, the complexity of performing this verification would be exponential in the size of the given NFA G .

Initial-state opacity is concerned with whether the external observer might be able to infer with

absolute certainty that the *initial* state of a given system definitely belonged in a set of secret *initial* states S_0 (which we can take without loss of generality to be a subset of the known possible initial states X_0). The intruder is assumed to have full knowledge of the system model and to be able to track the sequence of observations that are generated by underlying activity in the system. Initial-state opacity holds if, regardless of the underlying activity in the system, the external observer is never able to determine that the system definitely started from an initial state in the set S_0 . The following is the formal definition of initial-state opacity (Saboori and Hadjicostis 2008).

Definition 4 (Initial-State Opacity) Consider an NFA $G = (X, \Sigma, \delta, X_0)$, along with a natural projection map P with respect to the set of observable events Σ_{obs} . We say that G is initial-state opaque with respect to a set of secret initial states S_0 , $S_0 \subseteq X_0$, if for each $t \in L(G, S_0)$, we can find $s \in L(G, NS_0)$ (where $NS_0 = X_0 \setminus S_0$ is the set of non-secret initial states) such that $P(t) = P(s)$.

The verification of initial-state opacity in Saboori and Hadjicostis (2008, 2013) is done using an initial-state estimator, which acts much like an observer but for the initial-state estimates rather than the current-state estimates. Since the construction of the initial-state estimator is worst-case exponential with respect to the square of the number of states in the system, this approach has complexity that is generally exponential in the square of the size of the given NFA G (more precisely, exponential in $|X_0| \times |X|$). Initial-state opacity has been shown to be a PSPACE complete problem (see, e.g., Saboori and Hadjicostis 2013), and it is unlikely that a polynomial algorithm for its verification exists.

Example 2 Considering NFA G from Example 1 (top of Fig. 1), we easily see from its observer G_{obs} (at the bottom of the figure) that G is current-state anonymous (no observer state corresponds to a singleton set).

If $S_0 = \{1, 2\}$, then NFA G is *not* initial-state opaque. To see this, consider the sequence of observations ad ; the only state trajectories that

match the observation ad are $1 \xrightarrow{a} 3 \xrightarrow{d} 2$, $1 \xrightarrow{a} 3 \xrightarrow{d} 2 \xrightarrow{c} 1$, $2 \xrightarrow{c} 1 \xrightarrow{a} 3 \xrightarrow{d} 2$, and $2 \xrightarrow{c} 1 \xrightarrow{a} 3 \xrightarrow{d} 2 \xrightarrow{c} 1$ and clearly indicate that the initial-state estimate is $\{1, 2\}$, which violates initial-state opacity.

If $S'_0 = \{1, 3\}$, then the system is initial-state opaque. To verify this, one can construct the initial-state estimator. [In this particular example, we observe that (i) if the first observation is a or b , then the initial-state estimate will be $\{1, 2\}$ and will remain $\{1, 2\}$ regardless of subsequent observations or (ii) if the first observation is d , then the initial-state estimate will be $\{3, 4\}$ and will remain $\{3, 4\}$ regardless of subsequent observations. In both cases, initial-state opacity holds.]

Remark 3 State-based notions of opacity have an inverse relationship to notions of observability/detectability. For example, detectability in a DES requires that *eventually* (i.e., after a finite number of observations) the state of a given NFA becomes known exactly to the external observer (Shu et al. 2007). Clearly, detectability is inversely related to current-state anonymity; however, the two notions are not exact opposites: a system that is current-state anonymous cannot be detectable, but not necessarily the other way around.

Language-Based Opacity

Given an NFA G , language-based or trace-based opacity is defined with respect to secret behavior that is captured by a sublanguage of G .

Definition 5 (Language-Based Opacity) Consider an NFA $G = (X, \Sigma, \delta, X_0)$, along with a natural projection map P with respect to the set of observable events Σ_{obs} . Given a secret language L_S , $L_S \subseteq L(G)$, and a non-secret language L_{NS} , $L_{NS} \subseteq L(G)$ (typically, $L_{NS} = L(G) \setminus L_S$), we say that language-based opacity holds for G if for all $t \in L_S$, there exists another string $s \in L_{NS}$ such that $P(t) = P(s)$.

In words, any secret sequence of events $t \in L_S$ appears to the external observer in a way that is identical to the appearance of at least one other non-secret sequence of events $s \in L_{NS}$. For regular languages, one can verify language-

based opacity by reducing it (with polynomial complexity) to an initial-state opacity problem (Wu and Lafortune 2013).

Weak Notions of Opacity

Weak notions of opacity significantly relax the requirements for the (strong) opacity notions that were described earlier. Note that if a system is strongly opaque in some sense, then it is also weakly opaque in the same sense (but not necessarily the other way around). Unlike strong notions of opacity, most weak notions of opacity can be verified with polynomial complexity. Below, we provide the definition for weak language-based opacity; other weak notions of opacity can be defined in a similar manner. For technical reasons, we require that the underlying NFA is deadlock-free so that any sequence of events in its language can be extended arbitrarily.

Definition 6 (Weak Language-Based Opacity) Consider a deadlock-free NFA $G = (X, \Sigma, \delta, X_0)$, along with a natural projection map P with respect to the set of observable events Σ_{obs} . Given a secret language L_S , $L_S \subseteq L(G)$, and a non-secret language L_{NS} , $L_{NS} \subseteq L(G)$ (typically, $NS = L(G) \setminus S$), we say that weak language-based opacity holds for G if there exists an arbitrary long $t \in L_S$, for which we can find another string $s \in L_{NS}$ such that $P(t) = P(s)$.

In words, weak language-based opacity only requires the presence of two (arbitrarily long) strings with the same projection, one belonging to the secret language and one belonging to the non-secret language.

Opacity Enforcement and Label Insertion

Researchers have considered two distinct ways for dealing with systems in which an opacity notion of interest is violated. The first methodology relies on (minimally) restricting the behavior of the system via supervisory control techniques (refer to ► “Supervisory Control by Wonham”) in a way that ensures that opacity is not violated.

This is achieved by disabling the occurrence of certain events that may lead to opacity violations. The second methodology is to use obfuscation techniques to modify (as necessary) the sequence of outputs that is generated by the system, so that the external observer cannot deduce a violation of opacity; in other words, there is no restriction on the behavior of the system, but one has to be careful on how to modify the output sequence so as to consistently confuse the external observer regarding the occurrence of secret behavior.

Enforcement of opacity via supervisory control strategies was pursued for many notions of opacity in finite automata. For example, the work in Badouel et al. (2007) considers how opacity can be enforced via supervisory control in the presence of multiple intruders, whereas the work in Dubreil et al. (2010) considers a single intruder that might observe different events than the ones observed/controlled by the supervisor. The work in Saboori and Hadjicostis (2012) considers how to enforce current-state opacity in partially observed NFAs, whereas Tong et al. (2018) consider settings where the relationship between three important sets of events (events observable by the intruder, events observable by the controller, events controllable by the controller) can be more general than in earlier works.

While supervisory control methods can be successful in enforcing opacity, they restrict the possible behavior of the system. An alternative approach is to *alter* the observations that are emitted by the system, in an effort to confuse the intruder. For example, the works in Wu and Lafortune (2014, 2015) and Ji et al. (2018) devise insertion functions to insert one or more labels in between observable events. Naturally, what is challenging in this case is to ensure that the insertion of labels appears to the intruder to be consistent with (non-secret) system behavior (and that this consistency can be maintained regardless of subsequent system activity). A related approach that enforces opacity at runtime by exploiting delay (i.e., by presenting delayed information to the intruder) was considered in Falcone and Marchand (2015).

Summary and Future Directions

One limitation of the notions of opacity that have been described so far is that they fail to provide a *quantifiable* measure of opacity for a given system; instead they simply provide a binary characterization of the system (being opaque or not opaque). In stochastic settings, however, one may have additional information about the probability with which different behavior occurs in the system. This can help us refine notions of opacity in two distinct ways.

Prior Probability for Opacity Violation: One can still maintain the criteria used for the (strong) notions of opacity described earlier but ask about the (prior) probability with which these criteria will be violated. For example, if we are interested in violations of current-state opacity, we can identify all executions that lead to a violation of current-state opacity and calculate the total (prior) probability with which such problematic behavior will occur. This prior probability will be zero if the given system is strongly current-state opaque; however, even if the system is not current-state opaque, it could be that the probability of behavior that leads to current-state opacity violations is acceptably small. The notions of *step-based almost current-state opacity* and *almost current-state opacity* that appeared in Saboori and Hadjicostis (2014) for probabilistic finite automata fall in this category; both of these notions can be verified with complexity that is exponential in the size of the given PFA (Saboori and Hadjicostis 2014).

Posterior Probability of Opacity Violation: Another shortcoming of the strong notions of opacity described earlier is that they do not attempt to characterize the confidence of the intruder (whether opacity is violated or not). Consider, for example, current-state opacity with respect to a set of secret states S . In a probabilistic system, it might be that the observer cannot be absolutely certain that the current state of the system belongs to the secret set S , but it is possible that the posterior probability (conditioned on a particular sequence of observations) that the state of the

system does not belong to S is very small. The notion of *probabilistic current-state opacity* that appeared in Saboori and Hadjicostis (2014) for probabilistic finite automata falls in this category; probabilistic current-state opacity is generally undecidable (Saboori and Hadjicostis 2014).

Being an important and generally applicable security/privacy notion, opacity has naturally emerged in many other types of DES. Some of the very first opacity considerations in dynamical systems involved transition systems or Petri nets (see, e.g., Bryans et al. 2005, 2008) and led, in many cases, to undecidability results. Opacity considerations in Petri nets also resurfaced more recently: for instance, Tong et al. (2017b) exploit the notions of basis markings and basis reachability graphs to efficiently verify current-state opacity in bounded Petri nets, whereas Tong et al. (2017a) deal with decidable and undecidable problems in the verification of certain opacity properties in Petri nets.

Other DES models that have been adopted for opacity studies include timed models (see, e.g., Cassez 2009) and, more recently, timed stochastic models (Lefebvre and Hadjicostis 2019) and cyber-physical systems (Yin and Zamani 2019).

Optimal Control and Mechanics

Anthony Bloch

Department of Mathematics, The University of Michigan, Ann Arbor, MI, USA

Abstract

There are very natural close connections between mechanics and optimal control as both involve variational problems. This is a huge subject and we just touch on some interesting connections here. A survey and history may be found in Sussman and Willems (1997). Other aspects may be found in Bloch (2003).

Keywords

Nonholonomic integrator · Sub-Riemannian optimal control · Variational problems

Variational Nonholonomic Systems and Optimal Control

Variational nonholonomic problems (i.e., constrained variational problems) are equivalent to optimal control problems under certain regularity conditions. This issue was investigated in Bloch and Crouch (1994), employing the classical results of Rund (1966) and Bliss (1930), which relate classical constrained variational problems to Hamiltonian flows, although not optimal control problems. We outline the simplest relationship and refer to Bloch (2003) for more details.

Let Q be a smooth manifold and TQ its tangent bundle with coordinates $(q^i, \dot{q}^i)$. Let $L : TQ \rightarrow \mathbb{R}$ be a given smooth Lagrangian and let $\Phi : TQ \rightarrow \mathbb{R}^{n-m}$ be a given smooth function. We consider the classical Lagrange problem:

$$\min_{q(\cdot)} \int_0^T L(q, \dot{q}) dt \quad (1)$$

subject to the fixed endpoint conditions $q(0) = 0$, $q(T) = q_T$ and subject to the constraints

$$\Phi(q, \dot{q}) = 0.$$

Consider a modified Lagrangian $\Lambda(q, \dot{q}, \lambda) = L(q, \dot{q}) + \lambda \cdot \Phi(q, \dot{q})$ with Euler–Lagrange equations

$$\frac{d}{dt} \frac{\partial \Lambda}{\partial \dot{q}}(q, \dot{q}, \lambda) - \frac{\partial \Lambda}{\partial q}(q, \dot{q}, \lambda) = 0, \quad \Phi(q, \dot{q}) = 0. \quad (2)$$

We can rewrite this equation in Hamiltonian form and show that the resulting equations are equivalent to the equations of motion given by the maximum principle for a suitable optimal control problem. Set $p = \frac{\partial \Lambda}{\partial \dot{q}}(q, \dot{q}, \lambda)$ and consider this equation together with the constraints $\Phi(q, \dot{q}) = 0$. We can solve these two equations for $(\dot{q}, \lambda)$ under suitable conditions as discussed in Bloch (2003). We obtain the standard Hamiltonian equations with $H(q, p) = p \cdot \phi(q, p) - L(q, \phi(q, p))$.

We now compare this to the optimal control problem

$$\min_{u(\cdot)} \int_0^T g(q, u) dt \quad (3)$$

subject to $q(0) = 0$, $q(T) = q_T$, $\dot{q} = f(q, u)$, where $u \in \mathbb{R}^m$ and f, g are smooth functions.

Then we have the following:

Theorem 1 *The Lagrange problem and optimal control problem generate the same (regular) extremal trajectories, provided that:*

- (i) $\Phi(q, \dot{q}) = 0$ if and only if there exists a u such that $\dot{q} = f(q, u)$.
- (ii) $L(q, f(q, u)) = g(q, u)$.

For the proof and more details, see Bloch (2003).

The n -Dimensional Rigid Body

An interesting mechanical example is the n -dimensional rigid body. See Manakov (1976) and Ratiu (1980).

One can introduce a related system which we will call *the symmetric representation of the rigid body*; see Bloch et al. (2002).

By definition, *the left invariant representation of the symmetric rigid body system* is given by the first-order equations

$$\dot{Q} = Q\Omega; \quad \dot{P} = P\Omega \quad (4)$$

where $Q, P \in SO(n)$ and where Ω is regarded as a function of Q and P via the equations

$$\Omega := J^{-1}(M) \in \mathfrak{so}(n) \quad \text{and} \quad M := Q^T P - P^T Q.$$

One can check that differentiating M yields the classical form of the n -dimensional rigid body equations. For more on the precise relationship, see Bloch et al. (2002).

Now we can link the symmetric representation of the rigid body equations with the theory of optimal control. This work, developed in Bloch and Crouch (1996) and more generally in Bloch et al. (2002), has been further extended to optimal control problems for the infinitesimal generators

of group actions (so-called Clebsch optimal control problems) in Gay-Balmaz and Ratiu (2011) and Bloch et al. (2011, 2013) and even further to a class of embedded control problems in Bloch et al. (2011, 2013).

Let $T > 0$, $Q_0, Q_T \in \text{SO}(n)$ be given and fixed. Let the rigid body optimal control problem be given by

$$\min_{U \in \mathfrak{so}(n)} \frac{1}{4} \int_0^T \langle U, J(U) \rangle dt \quad (5)$$

subject to the constraint on U that there be a curve $Q(t) \in \text{SO}(n)$ such that

$$\dot{Q} = QU \quad Q(0) = Q_0, \quad Q(T) = Q_T. \quad (6)$$

Proposition 1 *The rigid body optimal control problem has optimal evolution equations (4) where P is the costate vector given by the maximum principle.*

The optimal controls in this case are given by

$$U = J^{-1}(Q^T P - P^T Q). \quad (7)$$

Kinematic Sub-Riemannian Optimal Control Problems

Optimal control of underactuated kinematic systems give rise to very interesting mechanical systems.

The problem is referred to as sub-Riemannian in that it gives rise to a geodesic flow with respect to a singular metric (see the work of Strichartz (1983, 1987) and Montgomery (2002) and references therein). This problem has an interesting history in control theory (see Brockett 1973, 1981; Baillieul 1975). See also Bloch et al. (1994) and Sussmann (1996) and further references below.

We consider control systems of the form

$$\dot{x} = \sum_{i=1}^m X_i u_i, \quad x \in M, \quad u \in \Omega \subset \mathbb{R}^m, \quad (8)$$

where Ω contains an open subset that contains the origin, M is a smooth manifold of dimension

n , and each of the vector fields in the collection $F := \{X_1, \dots, X_k\}$ is complete.

We assume that the system satisfies the accessibility rank condition and is thus controllable, since there is no drift term. Then we can pose the optimal control problem

$$\min_{u(\cdot)} \int_0^T \frac{1}{2} \sum_{i=1}^m u_i^2(t) dt \quad (9)$$

subject to the dynamics (8) and the endpoint conditions $x(0) = x_0$ and $x(T) = x_T$. These problems were studied by Griffiths (1983) from the constrained variational viewpoint and from the optimal control viewpoint by Brockett (1981, 1983). In the sub-Riemannian geodesic problem, abnormal extremals play an important role. See work by Strichartz (1983), Montgomery (1994, 1995), Sussmann (1996), and Agrachev and Sarychev (1996).

Example: Optimal Control and a Particle in a Magnetic Field The control analysis of the Heisenberg model or nonholonomic integrator goes back to Brockett (1981) and Baillieul (1975), while a modern treatment of the relationship with a particle in a magnetic field may be found in Montgomery (1993), for example. A nice treatment of the pure mechanical aspects of a particle in a magnetic field may be found in Marsden and Ratiu (1999).

The Heisenberg optimal control equations are a particular case of planar charged particle motion in a magnetic field. This may be seen by considering the slightly more general problem below.

We now consider the optimal control problem

$$\min \int (u^2 + v^2) dt \quad (10)$$

subject to the equations

$$\begin{aligned} \dot{x} &= u, \\ \dot{y} &= v, \\ \dot{z} &= A_1 u + A_2 v, \end{aligned} \quad (11)$$

where $A_1(x, y)$ and $A_2(x, y)$ are smooth functions of x and y . $A_1 = y$ and $A_2 = -x$ recover the Heisenberg/nonholonomic integrator equations. More generally we get the flow of a particle in a magnetic field – it is not hard to carry out the optimal control analysis to see this. Details are in Bloch (2003).

Optimal Control and Pontryagin's Maximum Principle

Richard Vinter
Imperial College, London, UK

Abstract

Pontryagin's Maximum Principle is a set of conditions providing information about solutions to optimal control problems; that is, optimization problems with differential equation constraints. It unifies and extends many classical necessary conditions from the calculus of variations. This article provides an overview of the Maximum Principle, including free end-time and nonsmooth versions. A time-optimal control problem is solved, to illustrate its application.

Dynamic constraints · Hamiltonian system · Maximum principle · Nonlinear systems · Optimization

Optimal Control

A widely used framework for studying minimization problems, encountered in the optimal selection of flight trajectories and other areas of advanced engineering design and operation involving dynamic constraints, is to view them as special cases of the problem:

$$(P) \left\{ \begin{array}{l} \text{Minimize } J(x(\cdot), u(\cdot)) \\ \quad := \int_0^T L(t, x(t), u(t)) dt + g(x(0), x(T)) \\ \text{over measurable functions} \\ \quad u(\cdot) : [0, T] \rightarrow R^m \text{ and} \\ \quad \text{absolutely continuous functions} \\ \quad x(\cdot) : [0, T] \rightarrow R^n \text{ satisfying} \\ \quad \dot{x}(t) = f(t, x(t), u(t)) \text{ a.e.,} \\ \quad u(t) \in \Omega \text{ a.e.,} \\ \quad (x(0), x(T)) \in C, \end{array} \right.$$

the data for which comprise a number $T > 0$, functions $f : [0, T] \times R^n \times R^m \rightarrow R^n$, $L : [0, T] \times R^n \times R^m \rightarrow R$, and $g : R^n \times R^n \rightarrow R$ and sets $C \subset R^n \times R^n$ and $\Omega \subset R^m$.

It is assumed that set C has the functional inequality and equality constraint set representation

$$C = \{(x_0, x_1) \in R^n \times R^n : \\ \times \left\{ \begin{array}{l} \phi^i(x_0, x_1) \leq 0 \text{ for } i = 1, 2, \dots, k_1 \\ \psi^i(x_0, x_1) = 0 \text{ for } i = 1, 2, \dots, k_2 \end{array} \right\} \} \quad (1)$$

in which $\phi^i : R^n \times R^n \rightarrow R$, $i = 1, \dots, k_1$ and $\psi^i : R^n \times R^n \rightarrow R$, $i = 1, \dots, k_2$ are given functions.

A control function is a measurable function $u(\cdot) : [0, T] \rightarrow R^m$ satisfying $u(t) \in \Omega$ a.e. $t \in [0, T]$. A state trajectory $x(\cdot) : [0, T] \rightarrow R^n$ associated with a control function $u(\cdot)$ is a solution to the differential equation $\dot{x}(t) = f(t, x(t), u(t))$. A pair of functions $(x(\cdot), u(\cdot))$ comprising a control function $u(\cdot)$ and an associated state trajectory $x(\cdot)$ satisfying the condition $(x(0), x(T)) \in C$ is a feasible process. A feasible process $(\bar{x}(\cdot), \bar{u}(\cdot))$ which achieves the minimum of $J(x(\cdot), u(\cdot))$ over all feasible processes is called a minimizer.

Frequently, the initial state is fixed, i.e., C takes the form

$$C = \{x_0\} \times C_1 \text{ for some } x_0 \in R^n \text{ and some } C_1 \subset R^n.$$

In this case, the domain of the minimization problem (P) can be taken to be control functions since there is a unique state trajectory (with a fixed left endpoint) associated with a given control function. Allowing freedom in the choice of initial state introduces a flexibility into the formulation which is useful in some applications however.

Optimization problems involving dynamic constraints (such as, but not exclusively, those expressed as controlled differential equations) are known as optimal control problems. Various frameworks are available for studying such

problems. (P) is of special importance, since it embraces a wide range of significant dynamic optimization problems which are beyond the reach of traditional variational techniques and, at the same time, it is well suited to the derivation of general necessary conditions of optimality.

The Maximum Principle

Pontryagin's Maximum Principle, the centerpiece of optimal control theory, is a set of necessary conditions for a feasible process to be a minimizer. It came to prominence through a book by Pontryagin et al., published in 1961 and brought out in English translation, Pontryagin et al. (1962), one year later. It bears the name of Pontryagin, because of his position as leader of the research group at the Steklov Institute, Moscow, which achieved this advance. But the first proof is attributed to Boltyanskii.

For given $\lambda \geq 0$, define the Hamiltonian function $H_\lambda : [0, T] \times R^n \times R^n \times R^m \rightarrow R'$

$$H_\lambda(t, x, p, u) := p^T f(t, x, u) - \lambda L(t, x, u).$$

Theorem 1 (The Maximum Principle) *Let $(\bar{x}(\cdot), \bar{u}(\cdot))$ be a minimizer for (P). Assume that the following hypotheses are satisfied:*

- (i) g is continuously differentiable.
- (ii) $\phi^i, i = 1, \dots, k_1$ and $\psi^i, i = 1, \dots, k_2$, are continuously differentiable.
- (iii) L and f are continuous, $L(t, \cdot, u)$ and $f(t, \cdot, u)$ are continuously differentiable for each (t, u) , and there exist $\epsilon > 0$ and $k(\cdot) \in L^1$ such that

$$|L(t, x, u) - L(t, x', u)| + |f(t, x, u) - f(t, x', u)| \leq k(t)|x - x'|$$

for all $x, x' \in R^n$ such that $|x - \bar{x}(t)| \leq \epsilon$, $|x' - \bar{x}(t)| \leq \epsilon$, and $u \in \Omega$, a.e. $t \in [0, T]$

- (iv) Ω is a Borel set.

Then there exist a number λ ($\lambda = 0$ or 1), an absolutely continuous arc $p : [0, T] \rightarrow R^n$,

numbers $\alpha^i \geq 0$ for $i = 1, \dots, k_1$ and numbers β^i for $i = 1, \dots, k_2$ satisfying

$$(p(\cdot), \lambda, \{\alpha^i\}, \{\beta^i\}) \neq (0, 0, \{0, \dots, 0\}, \{0, \dots, 0\}) \quad (2)$$

and such that the following conditions are satisfied:

The Costate Equation:

$$\begin{aligned} -\dot{p}(t) &= \frac{\partial}{\partial x} f^T(t, \bar{x}(t), \bar{u}(t)) p(t) \\ &\quad - \lambda \frac{\partial}{\partial x} L^T(t, \bar{x}(t), \bar{u}(t)), \text{ a.e.,} \end{aligned}$$

The Maximization of the Hamiltonian Condition:

$$\begin{aligned} H_\lambda(t, \bar{x}(t), p(t), \bar{u}(t)) \\ = \max_{u \in \Omega} H_\lambda(t, \bar{x}(t), p(t), u) \text{ a.e.,} \end{aligned}$$

The Transversality Condition:

$$\begin{aligned} (p^T(0), -p^T(T)) &= \lambda \nabla g(\bar{x}(0), \bar{x}(T)) \\ &\quad + \sum_{i=1}^{k_1} \alpha^i \nabla \phi^i(\bar{x}(0), \bar{x}(T)) \\ &\quad + \sum_{i=1}^{k_2} \beta^i \nabla \psi^i(\bar{x}(0), \bar{x}(T)) \end{aligned}$$

and

$$\begin{aligned} \alpha^i &= 0 \text{ for all } i \in \{1, \dots, k_1\} \\ \text{s.t. } \phi^i(\bar{x}(0), \bar{x}(T)) &< 0, \end{aligned}$$

in which, for a generic function $h : R^n \times R^n \rightarrow R$,

$$\begin{aligned} \nabla h(x_0, x_1)(\bar{x}_0, \bar{x}_1) \\ := \left[\frac{\partial}{\partial x_0} h(\bar{x}_0, \bar{x}_1), \frac{\partial}{\partial x_1} h(\bar{x}_0, \bar{x}_1) \right]. \quad (3) \end{aligned}$$

If the functions $L(t, x, u)$ and $f(t, x, u)$ are independent of t , in which case H_λ no longer depends on t , the following condition is also satisfied

Constancy of the Hamiltonian for Autonomous Problems:

$H_\lambda(\bar{x}(t), p(t), \bar{u}(t)) = c \quad \text{a.e., for some constant } c.$

We allow the cases $k_1 = 0$ (no inequality constraints) and $k_2 = 0$ (no equality endpoint-constraints). In the first case, the non-degeneracy condition becomes $(p(\cdot), \lambda, \{\beta^i\}) \neq (0, 0, 0)$, and the summation involving the α^i 's is dropped from the transversality condition and non-triviality condition (2). The second case, or any combination of the two cases, is treated similarly.

Derivation of the costate equation and boundary conditions. A simple way to derive the differential equations for the $p_i(\cdot)$'s is, first, to construct the Hamiltonian $H_\lambda(t, x, p, u) = p^T f(t, x, u) - \lambda L(t, x, u)$ and, second, to use the fact that the i th component $p_i(\cdot)$ of the costate $p(t) = [p_1(t), \dots, p_n(t)]^T$ satisfies the equation:

$$-\dot{p}_i(t) = \frac{\partial}{\partial x_i} H_\lambda(t, \bar{x}(t), p(t), \bar{u}(t))$$

for $i = 1, \dots, n.$

The preceding equations are of course merely a component-wise statement of the costate equation above. In many applications the endpoint constraints take the form

$$\begin{aligned} x_i(0) &= \xi_0^i \text{ for } i \in J_0 \text{ and } x_i(0) \in R^n \text{ for } i \notin J_0 \\ x_i(T) &= \xi_1^i \text{ for } i \in J_1 \text{ and } x_i(T) \in R^n \text{ for } i \notin J_1 \end{aligned}$$

for given index sets $J_0, J_1 \subset \{0, \dots, n\}$ and n -vectors ξ_0^i for $i \in J_0$ and ξ_1^i for $i \in J_1$, i.e., the endpoints of each state trajectory component are either "fixed" or "free." In such cases the rules for setting up the boundary conditions on the $p_i(\cdot)$'s are

$$\begin{aligned} p_i(0) &\in R^n \text{ for } i \in J_0 \text{ and } p_i(0) = \lambda \frac{\partial}{\partial x_{0i}} g(\bar{x}(0), \bar{x}(T)) \text{ for } i \notin J_0 \\ p_i(T) &\in R^n \text{ for } i \in J_1 \text{ and } -p_i(T) = \lambda \frac{\partial}{\partial x_{1i}} g(\bar{x}(0), \bar{x}(T)) \text{ for } i \notin J_1, \end{aligned}$$

i.e., if $x_i(0)$ (respectively, $x_i(T)$) is fixed, then $p_i(0)$ (respectively, $p_i(T)$) is free, and if $x_i(0)$ (respectively, $x_i(T)$) is free, then $p_i(0)$ (respectively, $p_i(T)$) is fixed.

The optimal control problem (P) is a generalization of the following problem in the calculus of variations:

$$\left\{ \begin{array}{l} \text{Minimize } \int_0^T L(t, x(t), \dot{x}(t)) dt \\ \text{over absolutely continuous arcs } x(\cdot) : \\ [0, T] \rightarrow R^n \text{ satisfying} \\ (x(0), x(T)) = (a, b). \end{array} \right. \quad (4)$$

for given $L : [0, T] \times R^n \times R^n \rightarrow R$ and $(a, b) \in R^n \times R^n$. This problem is a special case of (P) in which $f(t, x, u) = u$, $\Omega = R^n$, $k_1 = 0$, $k_2 = 2n$ and

$$\begin{aligned} & \left((\psi^1(x_0, x_1), \dots, \psi^n(x_0, x_1)) \right), \\ & \left(\psi^{n+1}(x_0, x_1), \dots, \psi^{2n}(x_0, x_1) \right) \\ & = (x_0^T - a^T, x_1^T - b^T). \end{aligned}$$

It is a straightforward exercise to deduce from the Maximum Principle, in this special case, that a minimizer satisfies the classical Euler-Lagrange and Weierstrass conditions and also that the minimizer and associated costate arc satisfy Hamilton's system of equations, under an additional uniform convexity hypothesis on $L(t, x, \cdot)$. Thus, the Maximum Principle unifies many of the classical necessary conditions from the calculus of variations and, furthermore, validates them under reduced hypotheses. But it has far-reaching implications, beyond these

conditions, because it allows the presence of pathwise constraints on the velocities, expressed in terms of a controlled differential equation and a control constraint set, which are encountered in engineering design, econometrics, and other areas of application.

The Hamiltonian System

In favorable circumstances, we are justified in setting the cost multiplier $\lambda = 1$ and, furthermore, the maximization of the Hamiltonian condition permits us, for each t , to express u as a function $u^*(., .)$ of x and p :

$$u = u^*(t, x, p).$$

The Maximum Principle now asserts that a minimizing arc $\bar{x}(\cdot)$ is the first component of a pair of absolutely continuous functions $(\bar{x}(\cdot), p(\cdot))$ satisfying *Hamilton's system of equations*:

$$\begin{aligned} (-\dot{p}^T(t), \dot{\bar{x}}^T(t)) &= \nabla_{xp} H_1 \\ &\times (t, \bar{x}(t), p(t), u^*(t, \bar{x}(t), p(t))) \quad \text{a.e.,} \end{aligned} \quad (5)$$

in which $\nabla_{xp} H_1$ denotes the gradient of $H(t, x, p, u)$ w.r.t. the vector (x, p) variables for fixed (t, u) , together with the endpoint conditions

$$\begin{aligned} (\bar{x}(0), \bar{x}(T)) &\in C \text{ and} \\ (p^T(0), -p^T(T)) &= \lambda \nabla g(\bar{x}(0), \bar{x}(T)) \\ &+ \sum_{i=1}^{k_1} \alpha^i \nabla \phi^i(\bar{x}(0), \bar{x}(T)) + \sum_{i=1}^{k_2} \beta^i \nabla \psi^i(\bar{x}(0), \bar{x}(T)), \end{aligned}$$

for some nonnegative numbers $\{\alpha^i\}$ and numbers $\{\beta^i\}$ satisfying

$$\begin{aligned} \alpha^i &= 0 \text{ for all } i \in \{1, \dots, k_1\} \text{ s.t. } \phi^i(\bar{x}(0), \\ &\bar{x}(T)) < 0, \end{aligned}$$

where ∇g , $\nabla \phi$ and $\nabla \psi$ etc., are as defined in (3). The minimizing control satisfies the relation

$$\bar{u}(t) = u^*(t, \bar{x}(t), p(t)).$$

Notice that the first-order vector differential equation (5) is a system of $2n$ scalar, first-order differential equations. Let us suppose that $\bar{k}_1$ inequality endpoint constraints are active at $(\bar{x}(0), \bar{x}(T))$. Then, satisfaction of the active constraints and the transversality condition supply $2n + \bar{k}_1 + k_2$ equations for the boundary values of $(\bar{x}(\cdot), p(\cdot))$. Taking account of the fact that there are $\bar{k}_1 + k_2$ unknown endpoint multipliers, however, we see that the effective

number of endpoint constraints accompanying the differential equation (5) is

$$2n + \bar{k}_1 + k_2 - (\bar{k}_1 + k_2) = 2n.$$

Thus the set of $2n$ scalar first-order differential equations (5) giving rise to a “two-point boundary value problem” for $(\bar{x}, p)$ is fully determined in the sense that the number of individual boundary conditions matches the number first order scalar equations.

Refinements

Free-Time Problems Consider a variant on the “autonomous” case of problem (P) (L and f do not depend on t), call it (FT), in which the terminal time T is no longer fixed but is a choice variable along with the control function and the initial state, and the cost function is

$$\tilde{J}(T, x(\cdot), u(\cdot))$$

$$:= \int_0^T L(x(t), u(t))dt + \tilde{g}(T, x(0), x(T))$$

for some function $\tilde{g}(\cdot, \cdot, \cdot)$. Take a minimizer $(\bar{T}, \bar{x}(\cdot), \bar{u}(\cdot))$ for (FT) . Assume, in addition to hypotheses (i)–(iii), that $\mathcal{Q}$ is bounded and the function $k(\cdot)$ in (iii) is bounded. Then the Maximum Principle conditions (for data in which the end-time is frozen at $T = \bar{T}$) continue to be satisfied for some $p(\cdot) : [0, \bar{T}] \rightarrow R^n$ and λ , including the constancy of the Hamiltonian condition

$$H_\lambda(\bar{x}(t), p(t), \bar{u}(t)) = c \quad \text{a.e } t \in [0, \bar{T}]$$

for some constant c . But a new condition is required to reflect the extra degree of freedom in the new problem specification, namely, the free end-time. This is an additional transversality condition involving the constant value c of the Hamiltonian:

Free End-Time Transversality Condition: $c = \lambda \frac{\partial}{\partial T} g(\bar{T}, \bar{x}(0), \bar{x}(T))$.

Other Refinements Versions of the Maximum Principle are available to take account of pathwise functional inequality constraints on state variables (“pure” state constraints) and of both state and control variables (“mixed” constraints). Maximum Principle-like conditions have also been derived for optimal control problems in which the dynamic constraint takes the form of a retarded differential equation with control terms and in which the class of control functions is enlarged to include Dirac delta functions (“impulse” optimal control problems).

The Nonsmooth Maximum Principle

In early derivations of the Maximum Principle, it was assumed that the functions $f(t, x, u)$ and $L(t, x, u)$ were continuously differentiable

with respect to the x variable. A major research endeavor since the early 1970s has been to find versions of the Maximum Principle that remain valid when the functions $f(t, x, u)$ and $L(t, x, u)$ satisfy merely a “bounded slope” or, synonymously, a Lipschitz continuity condition with respect to x . Such functions are “nonsmooth” in the sense that they can fail to be differentiable, in the conventional sense, at some points in their domains. An overview of the Maximum Principle would be incomplete without reference to such advances.

The search for nonsmooth optimality conditions is motivated by a desire to solve optimal control problems where, in particular, the function $f(t, x, u)$ is a piecewise linear function of x (for fixed (t, u)). Such functions arise, for example, when the $f(t, x, u)$ is constructed empirically via a lookup table and linear interpolation. Nonsmooth cost integrands are encountered when they are constructed using “pointwise” supremum and/or “absolute value” operations. The function

$$J(x(\cdot)) = \int_0^T |x(t)|dt + \max\{x(1), 0\},$$

which penalizes the L^1 norm of the state trajectory and the terminal value of the scalar state, but only if this is nonnegative, is a case in point.

When attempting to generalize the Maximum Principle to allow for nonsmooth data, we encounter the challenge of interpreting the costate equation, which can be written as

$$-\dot{p}(t) = \frac{\partial}{\partial x} H_\lambda(t, \bar{x}(t), \bar{u}(t)p(t)),$$

in circumstances when the x -gradients of f and L are not defined, at least not in a conventional sense. One approach to dealing with this problem is via the Clarke generalized gradient ∂m of function $m: R^n \rightarrow R$ at a point $\bar{x}$:

$\partial m(\bar{x}) := \text{co} \{ \xi \mid \text{there exist sequences } x^i \rightarrow \bar{x}, \xi^i \rightarrow \xi \text{ s.t., for each } i,$

$m(\cdot)$ is Fréchet differentiable at x^i and $\xi_i = \frac{\partial}{\partial x} m(x^i) \}$.

Here, “co” means closed convex hull. In a landmark paper, *Clarke FH 76*, Clarke proved a necessary condition commonly referred to as the nonsmooth Maximum Principle, in which the costate equation is replaced by a differential inclusion involving the (partial) generalized gradient $\partial_x H(t, \bar{x}(t), p(t), \bar{u}(t))$ of $H(t, \cdot, p(t), \bar{u}(t))$ w.r.t x , evaluated at $\bar{x}(t)$, namely,

$$-\dot{p}^T(t) \in \partial_x H(t, \bar{x}(t), \bar{u}(t)) \quad \text{a.e. } t \in [0, T].$$

This formulation of the ‘costate inclusion’ for the nonsmooth Maximum Principle and the unrestrictive hypothesis under which it is derived in this paper remain state of the art. Another approach is based on the concept of ‘derivate containers’ *Warga J 83*.

Example

We illustrate the application of the Maximum Principle with a simple example. It has the fol-

lowing interpretation. A 1 kg mass is located 1 m along the line and has zero initial velocity. We seek a time $\bar{T} > 0$ s, which is the minimum over all times $T > 0$ having the property: there exists a time-varying force $u(t)$, $0 \leq t \leq T$ satisfying

$$-1 \leq u(t) \leq +1$$

such that, under the action of the force, the mass is located at the origin with zero velocity at time T . Note that, in consequence of Newton’s second law, the vector $x(t) = (x_1(t), x_2(t))$ comprising the displacement and velocity of the mass satisfies

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t). \quad (6)$$

This is a special case of the free end-time problem

$$\left\{ \begin{array}{l} \text{Minimize } T \\ \text{over times } T > 0, \text{ measurable functions } u(\cdot) : [0, T] \rightarrow R \text{ and} \\ \text{absolutely continuous functions } x(\cdot) : [0, T] \rightarrow R^2 \text{ such that} \\ \dot{x}(t) = Ax(t) + bu(t) \quad \text{a.e.} \\ u(t) \in \Omega \quad \text{a.e.} \\ (x_1(0), x_2(0)) = (1, 0) \text{ and } (x_1(T), x_2(T)) = (0, 0). \end{array} \right.$$

in which $A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$, $b = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ and $\Omega = [-1, +1]$.

The (free-time) Maximum Principle provides the following information about a minimizing end-time $\bar{T}$, control $\bar{u}(\cdot)$, and corresponding state $\bar{x}(\cdot) = (\bar{x}_1(\cdot), \bar{x}_2(\cdot))$. There exists an arc $p(\cdot) = [p_1(\cdot), p_2(\cdot)]^T$ such that

$$\dot{\bar{x}}_1(t) = \bar{x}_2(t) \quad \text{and} \quad \dot{\bar{x}}_2(t) = \bar{u}(t), \quad (7)$$

$$-\dot{p}_1(t) = 0 \quad \text{and} \quad -\dot{p}_2(t) = p_1(t), \quad (8)$$

$$\bar{u}(t) = \arg \max \{ p_2(t)u \mid u \in [-1, +1] \} \quad (9)$$

$$(\bar{x}_1, \bar{x}_2)(0) = (1, 0) \text{ and } (\bar{x}_1, \bar{x}_2)(T) = (0, 0) \quad (10)$$

$$p_1(t) \bar{x}_2(t) + |p_2(t)| = \lambda \quad \text{for all } t. \quad (11)$$

Condition (9) permits us to express $\bar{u}(\cdot)$ in terms of $p_2(\cdot)$, thus

$$\bar{u}(t) = \text{sign}\{p_2(t)\},$$

and thereby eliminate $\bar{u}(\cdot)$. It can be shown that relations (7), (8), (9), (10), and (11) have a unique solution for $\bar{T}$, $\bar{u}(t)$, $\bar{x}(t)$, $p(t)$ and $\lambda = 0$ or 1. Furthermore, these relations cannot be satisfied with $\lambda = 0$. The unique solution (with $\lambda = 1$) is

$$\bar{T} = 2$$

$$(\bar{x}_1(t), \bar{x}_2(t)) = \begin{cases} (1 - \frac{1}{2}t^2, -t) & \text{if } t \in [0, 1) \\ (\frac{1}{2} - (t-1) + \frac{1}{2}(t-1)^2 - 1 + \frac{1}{2}(t-1)), & \text{if } t \in [1, 2], \end{cases}$$

$$\bar{u}(t) = \begin{cases} -1 & \text{if } t \in [0, 1) \\ +1 & \text{if } t \in [1, 2], \end{cases}$$

$$p_1(t) = -1 \text{ and } p_2(t) = -1 + t \quad \text{for } t \in [0, 2].$$

The Maximum Principle is a necessary condition of optimality. Since a minimizer exists and since $(\bar{T}, \bar{x}(\cdot), \bar{u}(\cdot), p(\cdot))$ is a unique solution to the Maximum Principle relations, it follows that $(\bar{T}, \bar{x}(\cdot), \bar{u}(\cdot))$ is the solution to the problem.

This problem is amenable to simpler, more elementary, solution techniques. But the above solution is enlightening, because it highlights important generic features of the Maximum Principle. We see how the “maximization of the Hamiltonian condition” can be used to eliminate the control function and thereby to set up a two-point boundary problem for $\bar{x}(\cdot)$ and $p(\cdot)$ (a very nonclassical construction).

Optimal Control and the Dynamic Programming Principle

Maurizio Falcone

Dipartimento di Matematica, SAPIENZA –
Università di Roma, Rome, Italy

Abstract

This entry illustrates the application of Bellman's dynamic programming principle within the context of optimal control problems for continuous-time dynamical systems. The approach leads to a characterization of the optimal value of the cost functional, over all possible trajectories given the initial conditions, in terms of a partial differential equation called the Hamilton–Jacobi–Bellman equation. Importantly, this can be used to synthesize the corresponding optimal control input as a state-feedback law.

Introduction

The dynamic programming principle (DPP) is a fundamental tool in optimal control theory. It was largely developed by Richard Bellman in the 1950s (Bellman 1957) and has since been applied to various problems in deterministic and stochastic optimal control. The goal of optimal control is to determine the control function and the corresponding trajectory of a dynamical system which together optimize a given criterion usually expressed in terms of an integral along the trajectory (the cost functional) (Fleming and Rishel 1975; Macki and Strauss 1982). The function which associates with the initial condition

of the dynamical system the optimal value of the cost functional among all the possible trajectories is called the *value function*. The most interesting point is that via the dynamic programming principle, one can derive a characterization of the value function in terms of a nonlinear partial differential equation (the Hamilton–Jacobi–Bellman equation) and then use it to synthesize a feedback control law. This is the major advantage over the approach based on the Pontryagin Maximum Principle (PMP) (Boltyanskii et al. 1956; Pontryagin et al. 1962). In fact, the PMP merely gives necessary conditions for the characterization of the open-loop optimal control and of the corresponding optimal trajectory. The DPP has also been applied to construct approximation schemes for the value function although this approach suffers from the “curse of dimensionality” since one has to solve a nonlinear partial differential equation in a high dimension. Despite the elegance of the DPP approach, its practical application is limited by this bottleneck, and the solution of many optimal control problems has been accomplished instead via the two-point boundary value problem associated with the PMP.

The Infinite Horizon Problem

Let us present the main ideas for the classical *infinite horizon problem*. Let a controlled dynamical system be given by

$$\begin{cases} \dot{y}(s) = f(y(s), \alpha(s)) \\ y(t_0) = x_0. \end{cases} \quad (1)$$

where $x_0, y(s) \in \mathbb{R}^d$, and

$$\alpha : [t_0, T] \rightarrow A \subseteq \mathbb{R}^m,$$

with T finite or $+\infty$. Under the assumption that the control is measurable, existence and uniqueness properties for the solution of (1) are ensured by the Carathéodory theorem:

Theorem 1 (Carathéodory) Assume that:

1. $f(\cdot, \cdot)$ is continuous.
2. There exists a positive constant $L_f > 0$ such that

$$|f(x, a) - f(y, a)| \leq L_f |x - y|,$$

for all $x, y \in \mathbb{R}^d$, $t \in \mathbb{R}^+$ and $a \in A$.

3. $f(x, \alpha(t))$ is measurable with respect to t .

Then, there is a unique absolutely continuous function $y : [t_0, T] \rightarrow \mathbb{R}^d$ that satisfies

$$y(s) = x_0 + \int_{t_0}^s f(y(\tau), \alpha(\tau)) d\tau. \quad (2)$$

which is interpreted as the solution of (1).

Note that the solution is continuous, but only a.e. differentiable, so it must be regarded as a weak solution of (1). By the theorem above, fixing a control in the set of admissible controls

$$\alpha \in \mathcal{A} := \{\alpha : [t_0, T] \rightarrow A, \text{ measurable}\}$$

yields a unique trajectory of (1) which is denoted by $y_{x_0, t_0}(s; \alpha)$. Changing the control policy generates a family of solutions of the controlled system (1) with index α . Since the dynamics (1) are “autonomous,” the initial time t_0 can be shifted to 0 by a change of variable. So to simplify the notation for autonomous dynamics, we can set $t_0 = 0$ and we denote this family by $y_{x_0}(s; \alpha)$ (or even write it as $y(s)$ if no ambiguity over the initial state or control arises). It is customary in dynamic programming, moreover, to use the notations x and t instead of x_0 and t_0 (since x and t appear as variables in the Hamilton–Jacobi–Bellman equation).

Optimal control problems require the introduction of a *cost functional* $J : \mathcal{A} \rightarrow \mathbb{R}$ which is used to select the “optimal trajectory” for (1). In the case of the infinite horizon problem, we set $t_0 = 0$, $x_0 = x$, and this functional is defined as

$$J_x(\alpha) = \int_0^\infty g(y_x(s, \alpha), \alpha(s)) e^{-\lambda s} ds \quad (3)$$

for a given $\lambda > 0$. The function g represents the

running cost and λ is the *discount factor*, which can be used to take into account the reduced value, at the initial time, of future costs. From a technical point of view, the presence of the discount factor ensures that the integral is finite whenever g is bounded. Note that one can also consider the undiscounted problem ($\lambda = 0$) provided the integral is still finite. The goal of optimal control is to find an optimal pair (y^*, α^*) that minimizes the cost functional. If we seek optimal controls in open-loop form, i.e., as functions of t , then the Pontryagin Maximum Principle furnishes necessary conditions for a pair (y^*, α^*) to be optimal.

A major drawback of an open-loop control is that being constructed as a function of time, it cannot take into account errors in the true state of the system, due, for example, to model errors or external disturbances, which may take the evolution far from the optimal forecasted trajectory. Another limitation of this approach is that a new computation of the control is required whenever the initial state is changed.

For these reasons, we are interested in the so-called *feedback controls*, that is, controls expressed as functions of the state of the system. Under feedback control, if the system trajectory is perturbed, the system reacts by changing its control strategy according to the change in the state. One of the main motivations for using the DPP is that it yields solutions to optimal control problems in the form of feedback controls.

DPP for the Infinite Horizon Problem

The starting point of dynamic programming is to introduce an auxiliary function, the *value function*, which for our problem is

$$v(x) = \inf_{\alpha \in \mathcal{A}} J_x(\alpha), \quad (4)$$

where, as above, x is the initial position of the system. The value function has a clear meaning: it is the optimal cost associated with the initial position x . This is a reference value which can be useful to evaluate the efficiency of a control – if $J_x(\bar{\alpha})$ is close to $v(x)$, this means that $\bar{\alpha}$ is “efficient.”

Bellman's dynamic programming principle provides a first characterization of the value function.

Proposition 1 (DPP for the infinite horizon problem) *Under the assumptions of Theorem 1, for all $x \in \mathbb{R}^d$ and $\tau > 0$,*

$$v(x) = \inf_{\alpha \in \mathcal{A}} \left\{ \int_0^\tau g(y_x(s; \alpha), \alpha(s)) e^{-\lambda s} ds + e^{-\lambda \tau} v(y_x(\tau; \alpha)) \right\}. \quad (5)$$

Proof. Denote by $\bar{v}(x)$ the right-hand side of (5). First, we remark that for any $x \in \mathbb{R}^d$ and $\bar{\alpha} \in \mathcal{A}$,

$$\begin{aligned} J_x(\bar{\alpha}) &= \int_0^\infty g(\bar{y}(s), \bar{\alpha}(s)) e^{-\lambda s} ds \\ &= \int_0^\tau g(\bar{y}(s), \bar{\alpha}(s)) e^{-\lambda s} ds \\ &\quad + \int_\tau^\infty g(\bar{y}(s), \bar{\alpha}(s)) e^{-\lambda s} ds \\ &= \int_0^\tau g(\bar{y}(s), \bar{\alpha}(s)) e^{-\lambda s} ds + e^{-\lambda \tau} \\ &\quad \times \int_0^\infty g(\bar{y}(s + \tau), \bar{\alpha}(s + \tau)) e^{-\lambda s} ds \\ &\geq \int_0^\tau g(\bar{y}(s), \bar{\alpha}(s)) e^{-\lambda s} ds + e^{-\lambda \tau} v(\bar{y}(\tau)) \end{aligned}$$

(here, $y_x(s, \bar{\alpha})$ is abbreviated as $\bar{y}(s)$). Taking the infimum over all trajectories, first over the right-hand side and then the left of this inequality, yields

$$v(x) \geq \bar{v}(x) \quad (6)$$

To prove the opposite inequality, we recall that $\bar{v}$ is defined as an infimum, and so, for any $x \in \mathbb{R}^d$ and $\varepsilon > 0$, there exists a control $\bar{\alpha}_\varepsilon$ (and the corresponding evolution $\bar{y}_\varepsilon$) such that

$$\bar{v}(x) + \varepsilon \geq \int_0^\tau g(\bar{y}_\varepsilon(s), \bar{\alpha}_\varepsilon(s)) e^{-\lambda s} ds + e^{-\lambda \tau} v(\bar{y}_\varepsilon(\tau)). \quad (7)$$

On the other hand, the value function v being also defined as an infimum, for any $x \in \mathbb{R}^d$ and $\varepsilon > 0$, there exists a control $\tilde{\alpha}_\varepsilon$ such that

$$v(\bar{y}_\varepsilon(\tau)) + \varepsilon \geq J_{\bar{y}_\varepsilon(\tau)}(\tilde{\alpha}_\varepsilon). \quad (8)$$

Inserting (8) in (7), we get

$$\begin{aligned} \bar{v}(x) &\geq \int_0^\tau g(\bar{y}_\varepsilon(s), \tilde{\alpha}_\varepsilon(s)) e^{-\lambda s} ds \\ &\quad + e^{-\lambda \tau} J_{\bar{y}_\varepsilon(\tau)}(\tilde{\alpha}_\varepsilon) - (1 + e^{-\lambda \tau}) \varepsilon \\ &\geq J_x(\hat{\alpha}) - (1 + e^{-\lambda \tau}) \varepsilon \\ &\geq v(x) - (1 + e^{-\lambda \tau}) \varepsilon, \end{aligned} \quad (9)$$

where $\hat{\alpha}$ is a control defined by

$$\hat{\alpha}(s) = \begin{cases} \tilde{\alpha}_\varepsilon(s) & 0 \leq s < \tau \\ \tilde{\alpha}_\varepsilon(s - \tau) & s \geq \tau. \end{cases} \quad (10)$$

(Note that $\hat{\alpha}(\cdot)$ is still measurable). Since ε is arbitrary, (9) finally yields $\bar{v}(x) \geq v(x)$. $\square$

We observe that this proof crucially relies on the fact that the control defined by (10) still belongs to $\mathcal{A}$, being a measurable control. The possibility of obtaining an admissible control by joining together two different measurable controls is known as the *concatenation property*.

The Hamilton–Jacobi–Bellman Equation

The DPP can be used to characterize the value function in terms of a nonlinear partial differential equation. In fact, let $\alpha^* \in \mathcal{A}$ be the optimal control, and y^* the associated evolution (to simplify, we are assuming that the infimum is a minimum). Then,

$$v(x) = \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds + e^{-\lambda \tau} v(y^*(\tau)),$$

that is,

$$v(x) - e^{-\lambda \tau} v(y^*(\tau)) = \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds$$

so that adding and subtracting $e^{-\lambda \tau} v(x)$ and dividing by τ , we get

$$e^{-\lambda\tau} \frac{(v(x) - v(y^*(\tau)))}{\tau} + \frac{v(x)(1 - e^{-\lambda\tau})}{\tau} \\ = \frac{1}{\tau} \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds.$$

Assume now that v is regular. By passing to the limit as $\tau \rightarrow 0^+$, we have

$$\lim_{\tau \rightarrow 0^+} -\frac{v(y^*(\tau)) - v(x)}{\tau} \\ = -Dv(x) \cdot \dot{y}^*(x) = -Dv(x) \cdot f(x, \alpha^*(0)) \\ \lim_{\tau \rightarrow 0^+} v(x) \frac{(1 - e^{-\lambda\tau})}{\tau} = \lambda v(x) \\ \lim_{\tau \rightarrow 0^+} \frac{1}{\tau} \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds = g(x, \alpha^*(0))$$

where we have assumed that $\alpha^*(\cdot)$ is continuous at 0. Then, we can conclude

$$\lambda v(x) - Dv(x) \cdot f(x, \alpha^*) - g(x, \alpha^*) = 0 \quad (11)$$

where $\alpha^* = \alpha^*(0)$. Similarly, using the equivalent form

$$v(x) + \sup_{\alpha \in \mathcal{A}} \left\{ -\int_0^\tau g(y(s), \alpha(s)) e^{-\lambda s} ds \right. \\ \left. - e^{-\lambda\tau} v(y(\tau)) \right\} = 0$$

of the DPP and the inequality, this implies for any (continuous at 0) control $\alpha \in \mathcal{A}$,

$$\lambda v(x) - Dv(x) \cdot f(x, \alpha) - g(x, \alpha) \\ \leq 0, \quad \text{for every } \alpha \in \mathcal{A}. \quad (12)$$

Combining (11) and (12), we obtain the *Hamilton–Jacobi–Bellman equation* (or *dynamic programming equation*):

$$\lambda u(x) + \sup_{\alpha \in A} \{-f(x, \alpha) \cdot Du(x) - g(x, \alpha)\} = 0, \quad (13)$$

which characterizes the value function for the infinite horizon problem associated with minimizing (3). Note that given x , the value of a achieving the max (assuming it exists) corresponds to the control $a^* = \alpha^*(0)$, and this makes

it natural to interpret the argmax in (13) as the optimal feedback at x (see Bardi and Capuzzo Dolcetta (1997) for more details).

In short, (13) can be written as

$$H(x, u, Du) = 0$$

with $x \in \mathbb{R}^d$, and

$$H(x, u, p) = \lambda u(x) + \sup_{a \in A} \{-f(x, a) \cdot p - g(x, a)\}. \quad (14)$$

Note that $H(x, u, \cdot)$ is convex (being the sup of a family of linear functions) and that $H(x, \cdot, p)$ is monotone (since $\lambda > 0$). It is also easy to see that the solution u is not differentiable even when f and g are smooth functions (i.e., $f, g, \in C^\infty(\mathbb{R}^n, A)$), so we need to deal with weak solution of the Bellman equation. This can be done in the framework of viscosity solutions, a theory initiated by Crandall and Lions in the 1980s which has been successfully applied in many areas as optimal control, fluid dynamics, and image processing (see the books Barles (1994) and Bardi and Capuzzo Dolcetta (1997) for an extended introduction and numerous applications to optimal control). Typically viscosity solutions are Lipschitz continuous solutions so they are differentiable almost everywhere.

An Extension to the Minimum Time Problem

In the minimum time problem, we want to minimize the time of arrival of the state on a given *target set* $\mathcal{T}$. We will assume that $\mathcal{T} \subset \mathbb{R}^d$ is a closed set. Then our cost functional will be given by

$$J(x, \alpha) = t_x(\alpha)$$

where

$$t_x(\alpha) := \begin{cases} \min\{t : y_x(t, \alpha) \in \mathcal{T}\} & \text{if } y_x(t, \alpha) \in \mathcal{T} \\ & \text{for some } t \geq 0 \\ +\infty & \text{if } y_x(t, \alpha) \notin \mathcal{T} \\ & \text{for any } t \geq 0 \end{cases}$$

The corresponding value function is called the *minimum time function*

$$T(x) := \inf_{\alpha(\cdot) \in \mathcal{A}} t_x(\alpha(\cdot)). \quad (15)$$

The main difference with respect to the previous problem is that now the value function T will be finite valued only on a subset $\mathcal{R}$ which depends on the target, on the dynamics, and on the set of admissible controls.

Definition 1 The reachable set $\mathcal{R}$ is defined by

$$\mathcal{R} := \cup_{t>0} \mathcal{R}(t) = \{x \in \mathbb{R}^n : T(x) < +\infty\}$$

where, for $t > 0$, $\mathcal{R}(t) := \{x \in \mathbb{R}^n : T(x) < t\}$. The meaning is clear: $\mathcal{R}$ is the set of initial points which can be driven to the target in finite time. The system is said to be *controllable* on $\mathcal{T}$ if for all $t > 0$, $\mathcal{T} \subset \text{int}(\mathcal{R}(t))$ (here, $\text{int}(D)$ denotes the interior of the set D). Assuming controllability in a neighborhood of the target one gets the continuity of the minimum time function and under the assumptions made on f , A , and $\mathcal{T}$, one can prove some interesting properties:

- (i) $\mathcal{R}$ is open.
- (ii) T is continuous on $\mathcal{R}$.
- (iii) $\lim_{x \rightarrow x_0} T(x) = +\infty$, for any $x_0 \in \partial \mathcal{R}$.

Now let us denote by $\mathcal{X}_D$ the characteristic function of the set D . Using in $\mathcal{R}$ arguments similar to the proof of DPP in the previous section one can obtain the following DPP:

Proposition 2 (DPP for the minimum time problem) For any $x \in \mathcal{R}$, the value function satisfies

$$T(x) = \inf_{\alpha \in \mathcal{A}} \{t \wedge t_x(\alpha) + \mathcal{X}_{\{t \leq t_x(\alpha)\}} T(y_x(t, \alpha))\} \quad (16)$$

for any $t \geq 0$

and

$$T(x) = \inf_{\alpha \in \mathcal{A}} \{t + T(y_x(t, \alpha))\} \quad (17)$$

for any $t \in [0, T(x)]$

From the previous DPP, one can also obtain the following characterization of the minimum time function.

Proposition 3 Let $\mathcal{R} \setminus \mathcal{T}$ be open and $T \in C(\mathcal{R} \setminus \mathcal{T})$, then T is a viscosity solution of

$$\max_{a \in A} \{-f(x, a) \cdot \nabla T(x)\} = 1 \quad x \in \mathcal{R} \setminus \mathcal{T} \quad (18)$$

coupled with the natural boundary condition

$$\begin{cases} T(x) = 0 & x \in \partial \mathcal{T} \\ \lim_{x \rightarrow \partial \mathcal{R}} T(x) = +\infty \end{cases}$$

By the change of variable $v(x) = 1 - e^{-T(x)}$, one can obtain a simpler problem getting rid of the boundary condition on $\partial \mathcal{R}$ (which is unknown). The new function v will be the unique viscosity solution of an external Dirichlet problem (see Bardi and Capuzzo Dolcetta (1997) for more details), and the reachable set can be recovered a posteriori via the relation $\mathcal{R} = \{x \in \mathbb{R}^d : v(x) < 1\}$.

Further Extensions and Related Topics

The DPP has been extended from deterministic control problems to many other problems. In the framework of stochastic control problems where the dynamics are given by a diffusion, the characterization of the value function obtained via the DPP leads to a second-order Hamilton–Jacobi–Bellman equation (Fleming and Soner 1993; Kushner and Dupuis 2001). Another interesting extension has been made in differential games where the DPP is based on the delicate notion of nonanticipative strategies for the players and leads to a nonconvex nonlinear partial differential equation (the Isaacs equation) (Bardi and Capuzzo Dolcetta 1997). For a short introduction to numerical methods based on DP and exploiting the so-called “value iteration,” we refer the interested reader to the

Appendix A in Bardi and Capuzzo Dolcetta (1997) and to Kushner and Dupuis (2001) (see also the book Howard (1960) for the “policy iteration”).

Optimal Control via Factorization and Model Matching

Michael Cantoni

Department of Electrical and Electronic Engineering, The University of Melbourne, Parkville, VIC, Australia

Abstract

One approach to linear control system design involves the matching of input-output models with respect to a quantification of performance. The approach is based on a parametrization of all stabilizing feedback controllers for the given plant model. This parametrization, constructed from coprime factorizations of the plant, and spectral factorization methods for solving model-matching problems, are described in this article. Both impulse-response energy and worst-case energy-gain measures of controller performance are considered.

Keywords

Coprime factorization · $\mathcal{H}_2$ control · $\mathcal{H}_\infty$ control · Spectral factorization · Youla-Kučera controller parametrization

Introduction

Various linear control system design problems can be formulated in terms of the interconnection shown in Fig. 1; e.g., see Francis and Doyle (1987), Boyd and Barratt (1991), and Zhou et al. (1996). The linear system K is a *controller* (with input y and output $u - v_1$) to be designed for the given *generalized plant* model G . The generalized plant is constructed so that controller *performance* (i.e., the quality of K relative to

Optimal Control via Factorization and Model Matching, Fig. 1 Standard interconnection for controller design

specifications) can be quantified as a nonnegative functional of

$$H(G, K) = G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21}, \quad (1)$$

which relates the input w and the output z when $v_1 = 0$ and $v_2 = 0$. The control objective is to select K to minimize, or achieve a specified upper bound on, this measure of performance. Typically, *internal stability* is also required, which pertains to the signals v_1 and v_2 as discussed further below. The so-called $\mathcal{H}_2$ and $\mathcal{H}_\infty$ control problems are well-known examples. In the $\mathcal{H}_2$ problem, performance is quantified as the energy (resp. power) of z when w is impulsive (resp. unit white noise). In the $\mathcal{H}_\infty$ problem, performance is quantified as the worst-case energy gain from w to z , which can be used to reflect robustness to model uncertainty, among other things; see Zhou et al. (1996).

The special case of $G_{22} = 0$ leads directly to a (weighted) *model-matching* problem, as the performance map becomes $H(G, K) = G_{11} + G_{12}KG_{21}$, which exhibits *affine* dependence on K . As such, the design of K can be interpreted in terms of matching $G_{12}KG_{21}$ to $-G_{11}$ with respect to the scalar quantification of performance. It turns out that every internally stabilizable problem with $G_{22} \neq 0$ can also

be converted into a model-matching problem. The key ingredients in this transformation are coprime factorizations of the plant model. The role of these and other factorizations in a model-matching approach to $\mathcal{H}_2$ and $\mathcal{H}_\infty$ control problems is the focus of this entry.

For the sake of argument, finite-dimensional linear time-invariant systems are considered in terms of real-rational transfer functions in the *frequency domain*, as the existence of all factorizations employed is well understood in this setting. Indeed, constructions via state-space realizations of such transfer functions and corresponding Riccati equations are well known (Zhou et al. 1996). The merits of the model-matching approach pursued here are at least twofold: (i) the underlying algebraic input-output (i.e., transfer function) perspective extends to more abstract settings, including classes of distributed-parameter and time-varying systems (Desoer et al. 1980; Vidyasagar 1985; Curtain and Zwart 1995; Feintuch 1998; Quadrat 2006); and (ii) model matching is a convex problem for various measures of performance (including mixed indexes) and controller constraints. The latter can be exploited to devise numerical algorithms for controller optimization (Boyd and Barratt 1991; Dahleh and Diaz-Bobillo 1995; Qi et al. 2004).

First, some notational conventions regarding transfer functions and two measures of performance for control system design are defined. Coprime factorizations are then described within the context of a well-known parametrization of stabilizing controllers, originally discovered by Youla et al. (1976) and Kucera (1975). This yields an affine parametrization of performance maps for problems in standard form, and thus, a transformation to a model-matching problem. Finally, the role of spectral factorizations in solving model-matching problems with respect to impulse-response energy ($\mathcal{H}_2$) and worst-case energy-gain ($\mathcal{H}_\infty$) measures of performance is described.

Notation and Nomenclature

$\mathcal{R}$ generically denotes a linear space of matrices with given row and column dimensions (not denoted explicitly) and entries that are *proper* real-rational functions of the complex variable s ; i.e., $(\sum_{k=1}^m b_k s^k) / (\sum_{k=1}^n a_k s^k)$ for sets of real coefficients $\{a_k\}_{k=1}^n$ and $\{b_k\}_{k=1}^m$ with $m \leq n < \infty$. Henceforth, the compatibility of matrix dimensions is implicitly assumed in the matrix sums and products that arise. All matrices in $\mathcal{R}$ have (non-unique) “state-space” realizations of the form $C(sI - A)^{-1}B + D$, where A , B , C , and D are matrices with real valued entries. This form naturally arises in frequency-domain analysis of the *input-output* map associated with the time-domain model $\dot{x}(t) = Ax(t) + Bu(t)$, with initial condition $x(0) = 0$ and output equation $y(t) = Cx(t) + Du(t)$, where $\dot{x}$ denotes the time derivative of x and u is the input. The study of such linear time-invariant differential equation models via the Laplace transform and *multiplication* by real-rational transfer function matrices is fundamental in linear systems theory (Kailath 1980; Francis 1987; Zhou et al. 1996). $P \in \mathcal{R}$ has an inverse $P^{-1} \in \mathcal{R}$ (i.e., $PP^{-1} = P^{-1}P = I$ where I denotes the identity matrix) if and only if $\lim_{|s| \rightarrow \infty} P(s)$ is a nonsingular matrix (i.e., the matrix D in a state-space realization is invertible). The superscripts T and $*$ denote the transpose and complex conjugate transpose. For a matrix $Z = Z^*$ with complex entries, $Z > 0$ means $z^*Zz \geq \epsilon z^*z$ for some $\epsilon > 0$ and all complex vectors z of compatible dimension. $P^\sim(s) := P(-s)^T$, whereby $(P(j\omega))^* = P^\sim(j\omega)$ for all real ω with $j := \sqrt{-1}$. Zeros of transfer function denominators are called poles.

In subsequent sections, several subspaces of $\mathcal{R}$ are used to define and solve two standard linear control problems. The subspace $\mathcal{B} \subset \mathcal{R}$ comprises transfer functions that have no poles on the imaginary axis in the complex plane. For $P \in \mathcal{B}$, the scalar performance index

$$\|P\|_\infty := \max_{-\infty \leq \omega \leq \infty} \bar{\sigma}(P(j\omega)) \geq 0$$

is finite; the real number $\bar{\sigma}(Z)$ is the maximum singular value of the matrix argument Z . This index measures the worst-case energy-gain from an input signal u to the output signal $y = Pu$. Note that $\|P\|_\infty < \gamma$ if and only if $\gamma^2 I - P^\sim(j\omega)P(j\omega) > 0$ for all $-\infty \leq \omega \leq \infty$.

The subspace $\mathcal{S} \subset \mathcal{B} \subset \mathcal{R}$ consists of transfer functions that have no poles with positive real part. A transfer function in $\mathcal{S}$ is called *stable* because the corresponding input-output map is causal in the time domain, as well as bounded-in-bounded-out (in various senses). If $P \in \mathcal{S}$ is such that $P^\sim P = I$, then it is called *inner*. If $P, P^{-1} \in \mathcal{S}$, then both are called *outer*.

The symbol $\mathcal{L}$ denotes the subspace of *strictly-proper* transfer functions in $\mathcal{B}$; i.e., for every matrix entry the degree n of the denominator *exceeds* the degree m of the numerator. Observe that $P \in \mathcal{L}$ if and only if $P^\sim \in \mathcal{L}$ if and only if $P \in \mathcal{B}$ and $\lim_{|s| \rightarrow \infty} P(s) = 0$. Further, note that $P_1 P_2 \in \mathcal{L}$ and $P_3 P_1 \in \mathcal{L}$ for all $P_1 \in \mathcal{L}$ and $P_i \in \mathcal{B}, i = 2, 3$. The inner-product defined for every $P, P_1 \in \mathcal{L}$ by

$$\langle P_1, P \rangle := \frac{1}{2\pi} \int_{-\infty}^{\infty} \text{trace}(P_1^\sim(j\omega)P(j\omega))d\omega < \infty$$

induces the scalar performance index $\|P\|_2 := \sqrt{\langle P, P \rangle} \geq 0$. This is equal to the root-mean-square (energy) measure of the impulse response, and also to the covariance (power) of the output signal $y = Pu$ when the input signal u is unit white noise. By the properties $\text{trace}(Z_1 + Z_2) = \text{trace}(Z_1) + \text{trace}(Z_2)$ and $\text{trace}(Z_1 Z_2) = \text{trace}(Z_2 Z_1)$ of the matrix trace operator, it follows that $\langle P_1 + P_2, P_3 \rangle = \langle P_1, P_3 \rangle + \langle P_2, P_3 \rangle$ and

$$\langle P_1, P_2 P_3 \rangle = \langle P_2^\sim P_1, P_3 \rangle$$

$$= \langle P_1 P_3^\sim, P_2 \rangle$$

$$= \langle P_3^\sim, P_1^\sim P_2 \rangle$$

$$\text{for } P_i \in \mathcal{L}, i = 1, 2, 3. \quad (2)$$

The subspace $\mathcal{L} \subset \mathcal{B} \subset \mathcal{R}$ can be expressed as the direct sum $\mathcal{L} = \mathcal{H} + \mathcal{H}_\perp$, where $\mathcal{H} = \mathcal{L} \cap \mathcal{S}$ and $\mathcal{H}_\perp$ is the subspace of transfer functions in $\mathcal{L}$ that have no poles with negative real part. That is, given $P \in \mathcal{L}$, there is a unique decomposition $P = \Pi_+(P) + \Pi_-(P)$, with $\Pi_+(P) \in \mathcal{H}$ and $\Pi_-(P) \in \mathcal{H}_\perp$. Observe that $P \in \mathcal{H}$ if and only if $P^\sim \in \mathcal{H}_\perp$. It can be shown via Plancherel's theorem that $\langle P_1, P_2 \rangle = 0$ for $P_1 \in \mathcal{H}_\perp$ and $P_2 \in \mathcal{H}$. Finally, note that $P_1 P_2 \in \mathcal{H}$ and $P_3 P_1 \in \mathcal{H}$ for all $P_i \in \mathcal{H}$ and $P_i \in \mathcal{S}$, $i = 2, 3$.

called an *inner-outer factorization*, and $P^\sim P = (M^{-1})^\sim M^{-1}$ is called a *spectral factorization*, since $M, M^{-1} \in \mathcal{S}$. More generally, if $\mathcal{E} = \mathcal{E}^\sim \in \mathcal{B}$ satisfies $\mathcal{E}(s) > 0$ for s on the extended imaginary axis, then there exists a (non-unique) spectral factor $\Sigma, \Sigma^{-1} \in \mathcal{S}$ such that $\mathcal{E} = \Sigma^\sim \Sigma$. Similarly, there exists a co-spectral factor $\tilde{\Sigma}, \tilde{\Sigma}^{-1} \in \mathcal{S}$ such that $\mathcal{E} = \tilde{\Sigma} \tilde{\Sigma}^\sim$. State-space realization-based constructions via the solution of Riccati equations can be found in Zhou et al. (1996, Chapter 13), for example.

Coprime and Spectral Factorizations

Given $P \in \mathcal{R}$, the factorizations $P = NM^{-1} = \tilde{M}^{-1}\tilde{N}$ are said to be *doubly coprime* over $\mathcal{S}$ provided $N, M, \tilde{N}, \tilde{M}$ are all in $\mathcal{S}$ and there exist $U_0, V_0, \tilde{U}_0, \tilde{V}_0$ in $\mathcal{S}$ such that $\tilde{V}_0 U_0 = \tilde{U}_0 V_0$,

$$\begin{bmatrix} \tilde{V}_0 & -\tilde{U}_0 \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = I \quad \text{and} \quad \begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix} = I \quad (3)$$

all hold; i.e., $\begin{bmatrix} M^T & N^T \end{bmatrix}$ and $\begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}$ are right invertible in $\mathcal{S}$. Importantly, if the factorizations are coprime and $P \in \mathcal{S}$, then $M^{-1} = \tilde{V}_0 - \tilde{U}_0 P$ and $\tilde{M}^{-1} = V_0 - P U_0$ are in $\mathcal{S}$, as sums of products of transfer functions in $\mathcal{S}$; i.e., M and $\tilde{M}$ are outer. Doubly coprime factorizations over $\mathcal{S}$ always exist, but these are not unique. Constructions from state-space realizations can be found in Zhou et al. (1996, Chapter 6) and Francis (1987), for example. As mentioned above, coprime factorizations play a role in transforming a general controller synthesis problem into the special model matching problem. Specifically, such factorizations underlie the Youla-Kučera parametrization of internally stabilizing controllers presented in the next section.

Subsequently, a special coprime factorization proves to be useful. If $P^\sim(s)P(s) = (M^\sim(s))^{-1}N^\sim(s)N(s)M^{-1}(s) > 0$ for s on the extended imaginary axis (i.e., for $s = j\omega$ with $-\infty \leq \omega \leq \infty$), then it is possible to choose the factor N to be inner. In this case, if P is also an element of $\mathcal{S}$, then $P = NM^{-1}$ is

Affine Controller/Performance-Map Parametrization

With reference to Fig. 1, a generalized plant model $G = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \in \mathcal{R}$ is said to be *internally stabilizable* if there exists $K \in \mathcal{R}$ such that the nine transfer functions associated with the map from the vector of signals (w, v_1, v_2) to the vector of signals (z, u, y) are all elements of $\mathcal{S}$; only one of these is the performance map $H(G, K) = G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21}$. Accounting in this way for the influence of the fictitious signals v_1 and v_2 , and the behavior of the internal signals u and y , amounts to the following requirement: Given minimal state-space realizations, any nonzero initial condition response decays exponentially in the time domain when G and K are interconnected according to Fig. 1 with $w = 0$, $v_1 = 0$ and $v_2 = 0$. Not every $G \in \mathcal{R}$ is internally stabilizable in the sense just defined; for example, take G_{11} to have a pole with positive real part and $G_{21} = G_{12} = G_{22} = 0$. A necessary condition for stabilizability is $(I - G_{22}K)^{-1} \in \mathcal{R}$; i.e., the inverse must be proper. The latter always holds if G_{22} is strictly proper, as assumed henceforth to simplify the presentation. It is also assumed that G is internally stabilizable.

It can be shown that G is internally stabilized by K if and only if the standard feedback interconnection of G_{22} and K , corresponding to $w = 0$ in Fig. 1, is internally stable. That is, if and only if the transfer function

$$\begin{bmatrix} I & -K \\ -G_{22} & I \end{bmatrix} \in \mathcal{R}, \quad (4)$$

which relates u and y to v_1 and v_2 in line with the summing junctions shown at the interconnection points, has an inverse in $\mathcal{S}$; see Francis (1987, Theorem 4.2). Substituting the coprime factorizations $K = UV^{-1} = \tilde{V}^{-1}\tilde{U}$ and $G_{22} = NM^{-1} = \tilde{M}^{-1}\tilde{N}$, it follows that the inverse of (4) is an element of $\mathcal{S}$ if and only if

$$\begin{bmatrix} M & U \\ N & V \end{bmatrix}^{-1} \in \mathcal{S} \quad \Leftrightarrow \quad \begin{bmatrix} \tilde{V} & -\tilde{U} \\ -\tilde{N} & \tilde{M} \end{bmatrix}^{-1} \in \mathcal{S}. \quad (5)$$

The equivalent characterizations of internal stability in (5) lead directly to affine parametrizations of controllers and performance maps. Specifically, following the approach of Desoer et al. (1980), Vidyasagar (1985), and Francis (1987), suppose that the factorizations $G_{22} = NM^{-1} = \tilde{M}^{-1}\tilde{N}$ are *doubly coprime* in the sense that (3) holds for some $U_0, V_0, \tilde{U}_0, \tilde{V}_0 \in \mathcal{S}$ with $\tilde{V}_0 U_0 = \tilde{U}_0 V_0$. Then it follows that

$$\begin{aligned} \begin{bmatrix} \tilde{V}_0 & -\tilde{U}_0 \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & U_0 \\ N & V_0 \end{bmatrix} &= \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} \\ &= \begin{bmatrix} M & U_0 \\ N & V_0 \end{bmatrix} \begin{bmatrix} \tilde{V}_0 & -\tilde{U}_0 \\ -\tilde{N} & \tilde{M} \end{bmatrix}, \end{aligned} \quad (6)$$

since $0 = G_{22} - G_{22} = \tilde{M}^{-1}(\tilde{M}N - \tilde{N}M)M^{-1}$. Now using (6) and the internal stability condition (5), it can be shown that $K = UV^{-1}$ stabilizes G_{22} if and only if

$$U = (U_0 - MQ) \text{ and } V = (V_0 - NQ) \text{ with } Q \in \mathcal{S}.$$

Similarly, K stabilizes G_{22} if and only if $K = (\tilde{V}_0 - Q\tilde{N})^{-1}(\tilde{U}_0 - Q\tilde{M})$ with $Q \in \mathcal{S}$. Together, these constitute the so-called Youla-Kučera parametrizations of internally stabilizing controllers for G_{22} . Importantly, the coprime factors of the controller are affine functions of the stable but otherwise free parameter Q . Moreover, using (6), an affine parametrization of

the standard performance map (1) holds by direct substitution of either controller parametrization. Specifically,

$$\begin{aligned} H(G, K) &= G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21} \\ &= T_1 + T_2QT_3 \quad \text{with } Q \in \mathcal{S}, \end{aligned} \quad (7)$$

where $T_1 = G_{11} + G_{12}U_0\tilde{M}G_{21}$, $T_2 = -G_{12}M$ and $T_3 = \tilde{M}G_{21}$. Clearly, $T_1 \in \mathcal{S}$ since this is the performance map when $Q = 0 \in \mathcal{S}$. By the assumption that G is stabilizable, it follows that T_2 and T_3 are also elements of $\mathcal{S}$; see Francis (1987, Chapter 4). The so-called Q -parametrization of stable performance maps in (7) motivates the subsequent consideration of model-matching problems with respect to the standard measures of control system performance given by $\|\cdot\|_2$ and $\|\cdot\|_\infty$.

Model-Matching via Spectral Factorization

Bearing in mind the Q -parametrization (7), consider the following $\mathcal{H}_2$ model-matching problem, where $\inf$ denotes greatest lower bound (infimum) and $T_i \in \mathcal{S}$, $i = 1, 2, 3$:

$$\inf_{Q \in \mathcal{S}} \|T_1 + T_2QT_3\|_2. \quad (8)$$

Assume that $T_2(s)$ and $T_3(s)$ have full column and row rank, respectively, for s on the extended imaginary axis and that T_1 is strictly proper. Then Q must be strictly proper, and thus an element of $\mathcal{H} \subset \mathcal{S}$, in order for the $\|\cdot\|_2$ measure of performance to be finite. Under this standard collection of assumptions, the infimum in (8) is achieved, as shown below.

By the definition of $\|\cdot\|_2$, a minimizer of the nonnegative convex functional $f := Q \in \mathcal{H} \mapsto \langle (T_1 + T_2QT_3), (T_1 + T_2QT_3) \rangle$ is a solution of the model matching problem. Given spectral factorizations $\Phi^* \Phi = T_2^* T_2$ and $\Lambda \Lambda^* = T_3 T_3^*$, which exist by the rank assumptions on T_2 and T_3 , define $R := \Phi Q \Lambda$ and $W := \Phi^* T_2^* T_1 T_3^* \Lambda^*$. Then for $Q \in \mathcal{H}$,

which is equivalent to $R \in \mathcal{H}$ by the property $\Phi, \Phi^{-1}, \Lambda, \Lambda^{-1} \in \mathcal{S}$ of the spectral factors, it follows that

$$\begin{aligned} f(Q) &= \langle T_1, T_1 \rangle + \langle \Phi^{-\sim} T_2^{\sim} T_1 T_3^{\sim} \Lambda^{-\sim}, R \rangle \\ &\quad + \langle R, \Phi^{-\sim} T_2^{\sim} T_1 T_3^{\sim} \Lambda^{-\sim} \rangle + \langle R, R \rangle \\ &= \langle T_1, T_1 \rangle + \langle W + R, W + R \rangle \\ &\quad - \langle W, W \rangle \\ &= \langle T_1, T_1 \rangle - \langle \Pi_+(W), \Pi_+(W) \rangle \\ &\quad + \langle (\Pi_+(W) + R), (\Pi_+(W) + R) \rangle, \end{aligned} \quad (9)$$

where the second equality holds by “completion-of-squares” and the last equality holds since $\langle \Pi_+(W), \Pi_-(W) \rangle = 0 = \langle R, \Pi_-(W) \rangle$. From (9) it is apparent that

$$Q = -\Phi^{-1} \Pi_+(\Phi^{-\sim} T_2^{\sim} T_1 T_3^{\sim} \Lambda^{-\sim}) \Lambda^{-1}$$

is a minimizer of f . As above, spectral factorization is a key component of the so-called Wiener-Hopf approach of Youla et al. (1976) and DeSantis et al. (1978).

Now consider the $\mathcal{H}_\infty$ model-matching problem

$$\inf_{Q \in \mathcal{S}} \|T_1 + T_2 Q T_3\|_\infty,$$

given $T_i \in \mathcal{S}$ for $i = 1, 2, 3$. This is more challenging than the problem (8). While sufficient conditions are available for the infimum to be achieved, computing a minimizer is generally difficult; see Francis and Doyle (1987) and Glover et al. (1991). In view of this, nearly optimal solutions are often sought by considering the relaxed problem of finding the set of $Q \in \mathcal{S}$ that satisfy $\|T_1 + T_2 Q T_3\|_\infty < \gamma$ for a value of $\gamma > 0$ greater than, but close to, the infimum.

With a view to highlighting the role of factorization methods and simplifying the presentation, suppose that T_2 is inner, which is possible without loss of generality via inner-outer factorization when $T_2(s)$ has full column rank for s on the extended imaginary axis. Further, assume that $T_3 = I$. Now following the approach

of Francis (1987) and Green et al. (1990), let $X^{\sim} = [X_1^{\sim} \ X_2^{\sim}] := [T_2 \ I - T_2 T_2^{\sim}] \in \mathcal{B}$, so that $X^{\sim} X = I$ and $X T_2 = \begin{bmatrix} I \\ 0 \end{bmatrix}$. Then,

$$\begin{aligned} \|T_1 + T_2 Q\|_\infty &= \|X(T_1 + T_2 Q)\|_\infty \\ &= \left\| \begin{bmatrix} T_2^{\sim} T_1 + Q \\ (I - T_2 T_2^{\sim}) T_1 \end{bmatrix} \right\|_\infty < \gamma \end{aligned} \quad (10)$$

if and only if

$$\begin{aligned} 0 &< \gamma^2 I - T_1^{\sim} (I - T_2 T_2^{\sim}) T_1 \\ &\quad - (T_2^{\sim} T_1 + Q)^{\sim} (T_2^{\sim} T_1 + Q) \end{aligned} \quad (11)$$

on the extended imaginary axis. Observing that (11) implies $0 < \gamma^2 I - T_1^{\sim} (I - T_2 T_2^{\sim}) T_1$, it can be shown that there exists $Q \in \mathcal{S}$ such that (10) holds if and only if the following are both satisfied: (a) there exists spectral factorization $\gamma^2 \Psi^{\sim} \Psi = \gamma^2 I - T_1^{\sim} (I - T_2 T_2^{\sim}) T_1$; and (b) there exists $\bar{R} (= Q \Psi^{-1}) \in \mathcal{S}$ such that $\|\bar{W} + \bar{R}\|_\infty < \gamma$, where $\bar{W} := T_2^{\sim} T_1 \Psi^{-1} \in \mathcal{B}$. The condition (b) is a well-known extension problem. A solution exists if and only if the induced norm of the Hankel operator with symbol $\bar{W}$ is less than γ , which is part of a result known as Nehari’s theorem. In fact, (b) is equivalent to the existence of (J) -spectral factor $\Upsilon, \Upsilon^{-1} \in \mathcal{S}$ with $\Upsilon_{11}^{-1} \in \mathcal{S}$ such that

$$\Upsilon^{\sim} \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \Upsilon = \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix}^{\sim} \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix}, \quad (12)$$

in which case $\|\bar{W} + \bar{R}\|_\infty \leq \gamma$ if and only if $\bar{R} = \bar{R}_1 \bar{R}_2^{-1}$ with $\begin{bmatrix} \bar{R}_1^T & \bar{R}_2^T \end{bmatrix} := \begin{bmatrix} \bar{S}^T & I \end{bmatrix} \Upsilon^{-T}$, $\bar{S} \in \mathcal{S}$ and $\|\bar{S}\|_\infty \leq \gamma$; see Ball and Ran (1987), Francis (1987), and Green et al. (1990) for details, including state-space realization-based constructions of the factors via Riccati equations. Noting that

$$\begin{aligned} &\begin{bmatrix} T_2 & T_1 \end{bmatrix}^{\sim} \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} T_2 & T_1 \end{bmatrix} \\ &= \begin{bmatrix} I & 0 \\ 0 & \Psi \end{bmatrix}^{\sim} \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix}^{\sim} \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & \Psi \end{bmatrix}, \end{aligned}$$

it follows using (12) that there exists $Q \in \mathcal{S}$ such that (10) holds if and only if there exists (J -)spectral factor Ω , $\Omega^{-1} \in \mathcal{S}$ with $\Omega_{11}^{-1} \in \mathcal{S}$ ($\Omega = \Upsilon \begin{bmatrix} I & 0 \\ 0 & \psi \end{bmatrix}$) that satisfies

$$\begin{bmatrix} T_2 & T_1 \\ 0 & I \end{bmatrix} \sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} T_2 & T_1 \\ 0 & I \end{bmatrix} \\ = \Omega \sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \Omega, \quad (13)$$

in which case $\|T_1 + T_2 Q\|_\infty \leq \gamma$ if and only if $Q = Q_1 Q_2^{-1}$, where $\begin{bmatrix} Q_1^T & Q_2^T \end{bmatrix} := \begin{bmatrix} S^T & I \end{bmatrix} \Omega^{-T}$, $S \in \mathcal{S}$ and $\|S\|_\infty \leq \gamma$; see Green et al. (1990). So-called J -spectral factorizations of the kind in (12) and (13) also appear in the chain-scattering/conjugation approach of Kimura (1989, 1997) and the factorization approach of Ball et al. (1991), for example.

Summary

The preceding sections highlight the role of coprime and spectral factorizations in formulating and solving model-matching problems that arise from standard $\mathcal{H}_2$ and $\mathcal{H}_\infty$ control problems. The transformation of standard control problems to model-matching problems hinges on an affine parametrization of internally stabilized performance maps. Beyond the problems considered here, this parametrization can be exploited to devise numerical algorithms for various other control problems in terms of convex mathematical programs.

Optimal Control with State Space Constraints

Heinz Schättler
Washington University, St. Louis, MO, USA

Abstract

Necessary and sufficient conditions for optimality in optimal control problems with state space constraints are reviewed with emphasis on geometric aspects.

Keywords

Admissible control · Bolza form · Mayer problem

Problem Formulation and Terminology

Many practical problems in engineering or of scientific interest can be formulated in the framework of optimal control problems with state space constraints. Examples range from the space shuttle reentry problem in aeronautics (Bonnard et al. 2003) to the problem of minimizing the base transit time in bipolar transistors in electronics (Rinaldi and Schättler 2003).

An optimal control problem with state space constraints in Bolza form takes the following form: minimize a functional

$$J(u) = \int_{t_0}^T L(t, x(t), u(t))dt + \Phi(T, x(T))$$

over all Lebesgue measurable functions $u : [t_0, T] \rightarrow U$ that take values in a control set $U \subset \mathbb{R}^m$, subject to the dynamics

$$\dot{x}(t) = F(t, x(t), u(t)), \quad x(t_0) = x_0,$$

terminal constraints

$$\Psi(T, x(T)) = 0,$$

and state space constraints

$$h_\alpha(t, x(t)) \leq 0 \quad \text{for } \alpha = 1, \dots, r.$$

The focus of this contribution is on state space constraints, and, for simplicity, in this formulation, we have omitted mixed control state space constraints of the form $g_\beta(t, x, u) \leq 0$. States x lie in $\mathbb{R}^n$ and controls in $\mathbb{R}^m$; typically, the control set $U \subset \mathbb{R}^m$ is compact and convex, often a polyhedron. The time-varying vector field $F : \mathbb{R} \times \mathbb{R}^n \times U \rightarrow \mathbb{R}^n$ is continuously differentiable in (t, x) , and the terminal constraint $N = \{(t, x) : \Psi(t, x) = 0\}$ is defined by continuously differentiable mappings $\psi_i : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^k$ with the property that the gradients $\nabla \psi_i = (\frac{\partial \psi_i}{\partial t}, \frac{\partial \psi_i}{\partial x})$ (which we write as row vectors) are linearly independent on N . The terminal time T can be free or fixed; a fixed terminal time simply would be prescribed by one of the functions ψ_i . The state space constraints

$$M_\alpha = \{(t, x) : h_\alpha(t, x) = 0\}, \quad \alpha = 1, \dots, r,$$

are defined by continuously differentiable time-varying vector fields $h_\alpha : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}$, $(t, x) \mapsto h_\alpha(t, x)$, and we assume that the gradients ∇h_α do not vanish on M_α . In particular, each set M_α thus is an embedded submanifold of codimension 1 of $\mathbb{R}^{n+1}$. We denote by $h = (h_1, \dots, h_r)^T$ the

time-varying vector field defining the state space constraints.

Terminology: *Admissible controls* are locally bounded Lebesgue measurable functions that take values in the control set, $u : [t_0, T] \rightarrow U$. Given any admissible control, the initial value problem $\dot{x}(t) = F(t, x(t), u(t))$, $x(t_0) = x_0$, has a unique solution defined on some maximal open interval of definition I . This solution is called the *trajectory* corresponding to the control u and the pair (x, u) is a *controlled trajectory*. An arc Γ of the graph of a trajectory defined over an open interval I for which none of the state space constraints is active is called an *interior arc*, and Γ is a *boundary arc* if at least one constraint is active on all of I . We call Γ an M_α -boundary arc over I if only the constraint $h_\alpha \leq 0$ is active on I . The times τ when interior arcs and boundary arcs meet are called *junction times* and the corresponding pairs $(\tau, x(\tau))$ *junction points*.

Despite the abundance and importance of practical problems that can be described as optimal control problems with state space constraints, for such problems the theory still lacks the coherence that the theory for problems without state space constraints has reached and there still exist significant gaps between the theories of necessary and sufficient conditions for optimality for optimal control problems with state space constraints. The theory of existence of optimal solutions differs little between optimal control problems with and without state space constraints, is well established, and will not be addressed here (e.g., see Cesari 1983 or the Filippov-Cesari theorem in Hartl et al. 1995).

Necessary Conditions for Optimality

First-order necessary conditions for optimality are given by the *Pontryagin maximum principle* (Pontryagin et al. 1962). The zero set of even a smooth (C^∞) function can be an arbitrary closed subset of the state space. As a result, in necessary conditions for optimality, the multipliers associated with the state space constraints a priori are only known to be nonnegative Radon measures

(Ioffe and Tikhomirov 1979; Vinter 2000). Let $u_* : [t_0, T] \rightarrow U$ be an optimal control with corresponding trajectory x_* and, for simplicity of presentation, also assume that no state constraints are active at the terminal time so that the standard transversality conditions apply. Then it follows that there exist a constant $\lambda_0 \geq 0$, an absolutely continuous function η , which we write as row-vector, $\eta : [t_0, T] \rightarrow (\mathbb{R}^n)^*$, and nonnegative Radon measures $\mu_\alpha \in C^*([t_0, T]; \mathbb{R})$, $\alpha = 1, \dots, r$, with support in the sets $R_\alpha = \{t \in [t_0, T] : h_\alpha(t, x_*(t)) = 0\}$, which do not all vanish simultaneously, i.e.,

$$\lambda_0 + \|\eta\|_\infty + \sum_{\alpha=1}^r \mu_\alpha([t_0, T]) > 0,$$

such that with

$$\lambda(t) = \eta(t) - \sum_{\alpha=1}^r \int_{[t_0, t]} \frac{\partial h_\alpha}{\partial x}(s, x_*(s)) d\mu_\alpha(s),$$

and

$$H = H(t, \lambda_0, \lambda, x, u) = \lambda_0 L(t, x, u) + \lambda F(t, x, u)$$

the following conditions hold:

(a) The adjoint equation holds in the form

$$\begin{aligned} \dot{\eta}(t) &= -\frac{\partial H}{\partial x}(t, \lambda_0, \lambda(t), x_*(t), u_*(t)) \\ &= -\lambda_0 \frac{\partial L}{\partial x}(t, x_*(t), u_*(t)) \\ &\quad - \lambda(t) \frac{\partial F}{\partial x}(t, x_*(t), u_*(t)), \end{aligned}$$

and there exists a row-vector $\mu \in (\mathbb{R}^k)^*$ such that

$$\lambda(T) = \lambda_0 \frac{\partial \Phi}{\partial x}(T, x_*(T)) + \mu \frac{\partial \Psi}{\partial x}(T, x_*(T))$$

and

$$\begin{aligned} 0 &= H(T, \lambda_0, \lambda(T), x_*(T), u_*(T)) \\ &\quad + \lambda_0 \frac{\partial \Phi}{\partial t}(T, x_*(T)) + \mu \frac{\partial \Psi}{\partial t}(T, x_*(T)). \end{aligned}$$

- (b) The optimal control minimizes the Hamiltonian over the control set U along $(\lambda(t), x_*(t))$:

$$\begin{aligned} & H(t, \lambda_0, \lambda(t), x_*(t), u_*(t)) \\ &= \min_{v \in U} H(t, \lambda_0, \lambda(t), x_*(t), v). \end{aligned}$$

Furthermore,

$$\begin{aligned} H(t, \lambda_0, \lambda(t), x_*(t), u_*(t)) \\ &= H(T, \lambda_0, \lambda(t), x_*(t), u_*(t)) \\ &\quad - \int_{[t, T]} \frac{\partial H}{\partial t}(s, \lambda_0, \lambda(s), x_*(s), u_*(s)) ds \\ &\quad + \sum_{\alpha=1}^r \int_{[t, T]} \frac{\partial h_\alpha}{\partial t}(s, x_*(s)) d\mu_\alpha(s) \end{aligned}$$

Controlled trajectories (x, u) for which there exist multipliers such that these conditions are satisfied are called *extremals*. In general, it cannot be excluded that λ_0 vanishes and extremals with $\lambda_0 = 0$ are called *abnormal*, while those with $\lambda_0 > 0$ are called *normal*. In this case, the multiplier can be normalized, $\lambda_0 = 1$.

Special Case: A Mayer Problem for Single-Input Control Linear Systems

Under the general assumptions formulated above, the sets $R_\alpha \subset [t_0, T]$ when a particular constraint is active can be arbitrarily complicated. But in many practical applications, state constraints have strong geometric properties – often they are embedded submanifolds – and it is possible to strengthen these necessary conditions for optimality in the sense of specifying the measures further. We formulate the conditions for a particular case of common interest.

We consider an optimal control problem in *Mayer form* (i.e., $L \equiv 0$) for a single-input control linear system with dynamics

$$\dot{x} = F(t, x, u) = f(t, x) + ug(t, x)$$

and the control set U a compact interval, $U = [a, b]$. Adjoining time as extra state variable, $i \equiv 1$, and defining

$$F_0(t, x) = \begin{pmatrix} 1 \\ f(t, x) \end{pmatrix} \text{ and } G(t, x) = \begin{pmatrix} 0 \\ g(t, x) \end{pmatrix},$$

for a continuously differentiable function $k : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^n$, the expressions

$$\begin{aligned} & \mathcal{L}_{F_0} k : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^n, \\ & (t, x) \mapsto (\mathcal{L}_{F_0} k)(t, x) \\ &= \frac{\partial k}{\partial t}(t, x) + \frac{\partial k}{\partial x}(t, x) f(t, x) \end{aligned}$$

and

$$\begin{aligned} & \mathcal{L}_G k : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^n, \\ & (t, x) \mapsto (\mathcal{L}_G k)(t, x) = \frac{\partial k}{\partial x}(t, x) g(t, x) \end{aligned}$$

represent the Lie (or directional) derivatives of the function k along the vector fields F_0 and G , respectively. In terms of this notation, the derivative of the function h_α (defining the manifold M_α) along trajectories of the system is given by

$$\begin{aligned} \dot{h}_\alpha(t, x(t)) &= \frac{d}{dt} h_\alpha(t, x(t)) \\ &= \mathcal{L}_{F_0} h_\alpha(t, x(t)) + u(t) \mathcal{L}_G h_\alpha(t, x(t)). \end{aligned}$$

If the function $\mathcal{L}_G h_\alpha$ does not vanish at a point $(\tilde{t}, \tilde{x}) \in M_\alpha$, then there exists a neighborhood V of $(\tilde{t}, \tilde{x})$ such that there exists a unique control $u_\alpha = u_\alpha(t, x)$ which solves the equation $\dot{h}_\alpha(t, x) = 0$ on V and u_α is given in feedback form as

$$u_\alpha(t, x) = -\frac{\mathcal{L}_{F_0} h_\alpha(t, x)}{\mathcal{L}_G h_\alpha(t, x)}.$$

The manifold M_α is said to be *control invariant of relative degree 1* if the Lie derivative of h_α with respect to G , $\mathcal{L}_G h_\alpha$, does not vanish anywhere on M_α and if the function $u_\alpha(t, x)$ is admissible, i.e., takes values in the control set $[a, b]$.

Thus, for a control-invariant submanifold of relative degree 1, the control that keeps the manifold invariant is unique, and the corresponding dynamics induce a unique flow on the constraint. This assumption corresponds to the least degenerate, i.e., in some sense most generic or common,

scenario and is satisfied for many practical problems.

Suppose the reference extremal is normal and let Γ_α be an M_α -boundary arc defined over an open interval I with corresponding boundary control u_α that takes values in the interior of the control set along Γ_α . Then the Radon measure μ_α is absolutely continuous with respect to Lebesgue measure on I with continuous and nonnegative Radon-Nikodym derivative $v_\alpha(t)$ given by

$$v_\alpha(t) = \frac{\lambda(t) \left(\frac{\partial g}{\partial t}(t, x_*(t)) + [f, g](t, x_*(t)) \right)}{\mathcal{L}_G h_\alpha(t, x_*(t))}$$

where $[f, g]$ denotes the Lie bracket of the time-varying vector fields f and g in the variable x ,

$$[f, g](t, x) = \frac{\partial g}{\partial x}(t, x)f(t, x) - \frac{\partial f}{\partial x}(t, x)g(t, x).$$

In particular, in this case, the adjoint equation can be expressed in the more common form

$$\dot{\lambda}(t) = -\lambda(t) \frac{\partial F}{\partial x}(t, x_*, u_*) - v_\alpha(t) \frac{\partial h_\alpha}{\partial x}(t, x_*),$$

with all partial derivatives evaluated along the reference trajectory. Furthermore, the multiplier λ remains continuous at entry or exit if the controlled trajectory (x_*, u_*) meets the constraint M_α transversally (e.g., see Schättler 2006). This follows from the following characterization of transversal connections between interior and boundary arcs due to Maurer (1977): if τ is an entry or exit junction time between an interior arc and an M_α -boundary arc for which the reference control u_* has a limit at τ along the interior arc, then the interior arc is transversal to M_α at entry or exit if and only if the control u_* is discontinuous at τ .

Informal Formulation of Necessary Conditions

In order to ensure the practicality of necessary conditions for optimality, it is essential that

besides atomistic structures at junctions that lead to computable jumps in the multipliers, the Radon measures μ_α have no singular parts with respect to Lebesgue measure. If it is *assumed* a priori that optimal controlled trajectories are finite concatenations of interior and boundary arcs, and if the constraint sets have a reasonably regular structure (embedded submanifolds and transversal intersections thereof) and satisfy a rather technical *constraint qualification* (see Hartl et al. 1995) that guarantees that the restrictions of the system to active constraints have solutions, then it is possible to specify the above necessary conditions further and formulate more user friendly versions for the determination of the multipliers. Such formulations have become the standard for numerical computations, but they still have not always been established rigorously and somewhat carry the stigma of a heuristic nature. Nevertheless, it is often this more concrete set of conditions that allow to solve problems numerically and analytically. If then, in conjunction with sufficient conditions for optimality, it is possible to verify the optimality of the computed extremal solutions, this generates a satisfactory theoretical procedure. Such conditions, following Hartl et al. (1995), generally are referred to as the “informal theorem”.

Suppose (x_*, u_*) is a normal extremal controlled trajectory defined over the interval $[t_0, T]$ with the property that the graph of x_* is a finite concatenation of interior and boundary arcs with junction times τ_i , $i = 1, \dots, k$, $t_0 = \tau_0 < \tau_1 < \dots < \tau_k < \tau_{k+1} = T$. Under an appropriate constraint qualification, there exist a multiplier λ , $\lambda : [t_0, T] \rightarrow (\mathbb{R}^n)^*$, which is absolutely continuous on each subinterval $[\tau_i, \tau_{i+1}]$; multipliers $v_\alpha, v_\alpha : [t_0, T] \rightarrow (\mathbb{R}^n)^*$, which are continuous on each interval $[\tau_i, \tau_{i+1}]$; a vector $\mu \in (\mathbb{R}^k)^*$; and vectors $\eta(\tau_i) \in (\mathbb{R}^r)^*$, $i = 1, \dots, k$, with nonnegative entries such that:

- (a) (adjoint equation) On each interval (τ_i, τ_{i+1}) , $i = 0, \dots, r$, λ satisfies the adjoint equation in the form

$$\begin{aligned}\dot{\lambda}(t) = & -\frac{\partial L}{\partial x}(t, x_*(t), u_*(t)) \\ & -\lambda(t) \frac{\partial F}{\partial x}(t, x_*(t), u_*(t)) \\ & -\sum_{\alpha=1}^r v_{\alpha}(t) \frac{\partial h_{\alpha}}{\partial x}(t, x_*),\end{aligned}$$

with $v_{\alpha}(t) = 0$ if the constraint M_{α} is not active at time t . Assuming that no state space constraint is active at the terminal time, the value of the multiplier λ at the terminal time is given by the transversality condition

$$\lambda(T) = \frac{\partial \Phi}{\partial x}(T, x_*(T)) + \mu \frac{\partial \Psi}{\partial x}(T, x_*(T)).$$

At any junction time τ_i between an interior arc and a boundary arc, the multiplier λ may be discontinuous satisfying a jump condition of the form

$$\lambda(\tau_i-) = \lambda(\tau_i+) + \eta(\tau_i) \frac{\partial h}{\partial x}(\tau_i, x_*(\tau_i))$$

and the complementary slackness condition

$$\eta(\tau_i) \frac{\partial h}{\partial x}(\tau_i, x_*(\tau_i)) = 0$$

holds.

- (b) The optimal control minimizes the Hamiltonian over the control set U along $(\lambda(t), x_*(t))$:

$$\begin{aligned}H(t, \lambda(t), x_*(t), u_*(t)) \\ = \min_{v \in U} H(t, \lambda(t), x_*(t), v)\end{aligned}$$

and at the junction times τ_i we have that

$$\begin{aligned}H(\tau_i, \lambda(\tau_i-), x_*(\tau_i), u_*(\tau_i-)) \\ = H(\tau_i, \lambda(\tau_i+), x_*(\tau_i), u_*(\tau_i+)) \\ - \eta(\tau_i) \frac{\partial h}{\partial t}(\tau_i, x_*(\tau_i)).\end{aligned}$$

Sufficient Conditions for Optimality

The literature on sufficient conditions for optimality for optimal control problems with state space constraints is limited. The value function for an optimal control problem at a point (t, x) in the extended state space, $V = V(t, x)$, is defined as the infimum over all admissible controls u for which the corresponding trajectory starts at the point x at time t and satisfies all the constraints of the problem,

$$V(t, x) = \inf_{u \in \mathcal{U}} J(u).$$

Any sufficiency theory for optimal control problems, one way or another, deals with the solution of the corresponding Hamilton-Jacobi-Bellman (HJB) equation:

$$\begin{aligned}\frac{\partial V}{\partial t}(t, x) + \min_{u \in U} \left\{ \frac{\partial V}{\partial x}(t, x) F(t, x, u) \right. \\ \left. + L(t, x, u) \right\} \equiv 0,\end{aligned}$$

$$V(T, x) = \Phi(T, x) \text{ whenever } \Psi(T, x) = 0.$$

Value functions for optimal control problems rarely are differentiable everywhere, but generally have singularities along lower-dimensional submanifolds. Nevertheless, under some technical assumptions and with proper interpretations of the derivatives, this equation describes the evolution of the value function of an optimal control problem and, if an appropriate solution can be constructed, indeed solves the optimal control problem.

There exists a broad theory of viscosity solutions to the HJB equation (e.g., Fleming and Soner 2005; Bardi and Capuzzo-Dolcetta 2008) that is also applicable to problems with state space constraints (Soner 1986) and, under varying technical assumptions, characterizes the value function V as the unique viscosity solution to the HJB equation. This has led to the development of algorithms that can be used to compute numerical solutions.

A more classical and more geometric approach to solving the HJB equation is based on the method of characteristics and goes back to the work of Boltyansky on a regular synthesis for optimal control problems without state space constraints (Boltyanskii 1966). This work follows classical ideas of fields of extremals from the calculus of variations and imposes technical conditions that allow to handle the singularities that arise in the value functions (e.g., see, Schättler and Ledzewicz 2012). Stalford's results in Stalford (1971) follow this approach for problems with state space constraints, but a broadly applicable theory of regular synthesis, as it was developed by Piccoli and Sussmann in (2000) for problems without state space constraints, does not yet exist for problems with state space constraints. Results that embed a controlled reference extremal into a local field of extremals have been given by

Bonnard et al. (2003) or Schättler (2006), and these constructions show the applicability of the concepts of a regular synthesis to problems with state space constraints as well.

Examples of Local Embeddings of Boundary Arcs

We illustrate the typical, i.e., in some sense most common, generic structures of local embeddings of boundary arcs in Figs. 1 and 2. The state constraint M_α is a control-invariant submanifold of relative degree 1 and represented by a horizontal line as it arises when limits on the size of a particular state are imposed. Figure 1 shows the typical entry-boundary-exit concatenations of an interior arc followed by a boundary arc and another interior arc. The local embedding of the boundary arc differs substantially from classical local imbeddings for unconstrained problems in the sense that this field necessarily contains

Optimal Control with State Space Constraints,

Fig. 1 A typical local synthesis around a boundary arc when no terminal constraints are present

Optimal Control with State Space Constraints,

Fig. 2 A typical local synthesis around a boundary arc when terminal constraints are present

small pieces of trajectories which, when propagated backward, are not close to the reference trajectory. This, however, does not affect the memoryless properties required for a synthesis forward in time, and strong local optimality of the reference trajectory can be proven combining synthesis type arguments with homotopy type approximations of the synthesis (Schättler 2006). The one trajectory marked as black line in Fig. 1 corresponds to an optimal trajectory that meets the constraint only at the junction point and immediately bounces back into the interior. Such a trajectory arises as the limit when the concatenation structure of optimal controlled trajectories changes from interior-boundary-interior arcs to trajectories that do not meet the constraint. These structures are one of the extra sources for singularities in the value function that come up in optimal control problems with state space constraints. Switching surfaces for the interior arcs, as one is also shown in this figure, do not cause such a loss of differentiability if they are crossed transversally by the extremal trajectories of the field.

Figure 2 depicts the structure of an optimal synthesis for a problem from electronics, the problem of minimizing the base transit time of bipolar homogeneous transistors. The electrical field that determines the transit time is controlled by tailoring a distribution of dopants in the base region, and this dopant profile becomes an important design parameter determining the speed of the device. But due to physical and engineering limitations, the variables describing the dopants need to be limited, and thus this becomes an optimal control problem with state space constraints represented by hard limits on the variables. The constraints here are control invariant of relative degree 1. Optimal solutions, in the presence of initial and terminal constraints, have both portions along the upper and lower control limits of the constrained variable and typically proceed from the upper to the lower values along an optimal singular control (which takes values in the interior of the control set) in the interior of the admissible domain, possibly with saturation if the control limits are reached.

Optimal Deployment and Spatial Coverage

Sonia Martínez

Department of Mechanical and Aerospace
Engineering, University of California, La Jolla,
San Diego, CA, USA

Abstract

Optimal deployment refers to the problem of how to allocate a finite number of resources over a spatial domain to maximize a performance metric that encodes certain quality of service. Depending on the deployment environment, the type of resource, and the metric used, the solutions to this problem can greatly vary.

Keywords

Coverage control algorithms · Facility location problems

Introduction

The problem of deciding what are optimal geographic locations to place a set of facilities has a long history and is the main subject in operations research and management science; see Drezner (1995). A facility can be broadly understood as a service such as a school; a hospital; an airport; an emergency service, such as a fire station; or, more generally, routes of a vehicle, from buses to aircraft, an autonomous vehicle, or a mobile sensor.

The specific formulation of facility location problems depends very much on the particular underlying application. A distinguishing feature is that all involve strategic planning, accounting for the long-term impact on the facility operating cost and their fast response to the demand. Thus, these problems lead to constrained optimization formulations which are typically very hard to solve optimally. The computational complexity of such problems, which, even in their most basic

formulations, typically lead to NP-hard problems, has made their solution largely intractable until the advent of high-speed computing.

Locational optimization techniques have also been employed to solve optimal estimation problems by static sensor networks, mesh and grid optimization design, clustering analysis, data compression, and statistical pattern recognition; see Du et al. (1999). However, these solutions typically require centralized computations and availability of information at all times.

When the facilities are multiple vehicles or mobile sensors, the underlying dynamics may require additional changes and further analysis that guarantee the overall system stability. In what follows, we review a particular coverage control problem formulation in terms of the so-called expected-value multicenter functions that makes the analysis tractable leading to robust, distributed algorithm implementations employing computational geometric objects such as Voronoi partitions.

Basic Ingredients from Computational Geometry

In order to formulate a basic optimal deployment problem and algorithm, we require of several notions from computational geometry; see Bullo et al. (2009) for more information.

Let S be a measurable set of $\mathbb{R}^m$, for $m \in \mathbb{N}$, consider a distance function d on $\mathbb{R}^m$, and let $P = \{p_1, \dots, p_n\}$ be n distinct points of S , corresponding to *locations* of certain facilities. The *Voronoi partition* of S generated by P and associated with d is given by $\mathcal{V}(P) = \{V_1(P), \dots, V_n(P)\}$, where

$$V_i(P) = \{q \in S \mid d(p_i, q) \leq d(p_j, q), \\ j \in P \setminus \{i\}\}, \quad i \in \{1, \dots, n\}.$$

Given $r \in \mathbb{R}_{>0}$, denote by $\overline{B}(p_i, r)$ the closed ball of center p_i and radius r . The *r-limited Voronoi partition* of S generated by P and associated with d is the Voronoi partition of

the set $S \cap \bigcup_{i=1}^n \overline{B}(p_i, r)$, denoted as $\mathcal{V}_r(P) = \{V_{1,r}(P), \dots, V_{n,r}(P)\}$.

Let $\phi : S \rightarrow \mathbb{R}_{\geq 0}$ be a measurable *density* function on S . The *area* and the *centroid* (or *center of mass*) of $W \subseteq S$ with respect to ϕ are the values

$$A_\phi(W) = \int_W \phi(q) dq,$$

$$CM_\phi(W) = \frac{1}{A_\phi(W)} \int_W q \phi(q) dq.$$

We say that the set of distinct points P in S is a *centroidal Voronoi configuration* (resp., a *r-limited centroidal Voronoi configuration*) if each p_i is at the centroid of its own Voronoi cell. That is, $p_i = CM_\phi(V_i(P))$, $i \in \{1, \dots, n\}$ (resp., $p_i = CM_\phi(V_{i,r}(P))$, and $i \in \{1, \dots, n\}$). Voronoi partitions and centroidal Voronoi configurations help assess the distribution of locations in a spatial domain as we establish below.

A Voronoi partition induces a natural *proximity graph*, called the *Delaunay graph*, over the set of points P . We recall that a *graph* G is a pair $G = (V, E)$ where V is a set of n vertices and E is a set of ordered pair of *vertices*, $E \subset V \times V$, called *edge set*. A *proximity graph* is a graph function defined on the set S , which assigns a set of distinct points $P \subset S$ to a graph $G(P) = (P, E(P))$, where $E(P)$ is a function of the relative locations of the point set. Example graphs include the following:

1. The *r-disk graph*, $\mathcal{G}_{\text{disk},r}$, for $r \in \mathbb{R}_{>0}$. Here, $(p_i, p_j) \in E_{\text{disk},r}(P)$ if $d(p_i, p_j) \leq r$.
2. The *Delaunay graph*, $\mathcal{G}_D$. We have $(p_i, p_j) \in E_D(P)$ if $V_i(P) \cap V_j(P) \neq \emptyset$.
3. The *r-limited Delaunay graph*, $\mathcal{G}_{\text{LD},r}$, for $r \in \mathbb{R}_{>0}$. Here, $(p_i, p_j) \in E_{\text{LD},r}(P)$ if $V_{i,r}(P) \cap V_{j,r}(P) \neq \emptyset$.

Expected-Value Multicenter Functions

Facility location problems consist of spatially allocating a number of sites to provide certain

quality of service. Problems of this class are formulated in terms of multicenter functions and, in particular, expected-value multicenter functions.

To define these, consider $\phi : S \rightarrow \mathbb{R}_{\geq 0}$ a density function over a bounded measurable set $S \subset \mathbb{R}^m$. One can regard ϕ as a function measuring the probability that some event takes place over the environment. The larger the value of $\phi(q)$, the more important the location q will have. We refer to a nonincreasing and piecewise continuously differentiable function $f : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}$, possibly with finite jump discontinuities, as a *performance function*.

Performance functions describe the utility of placing a node at a certain distance from a location in the environment. The smaller the distance, the larger the value of f , that is, the better the performance. For instance, in sensing problems, performance functions can encode the signal-to-noise ratio between a source with an unknown location and a sensor attempting to locate it. Without loss of generality, it can be assumed that $f(0) = 0$.

An *expected-value multicenter function* models the expected value of the coverage over any point in S provided by a set of points $p_1, \dots, p_n$. Formally,

$$\mathcal{H}(p_1, \dots, p_n) = \int_S \max_{i \in \{1, \dots, n\}} f(\|q - p_i\|_2) \phi(q) dq, \quad (1)$$

where $\|\cdot\|_2$ denotes the 2-norm of $\mathbb{R}^m$. This definition can be understood as follows: consider the best coverage of $q \in S$ among those provided by each of the nodes $p_1, \dots, p_n$, which corresponds to the value $\max_{i \in \{1, \dots, n\}} f(\|q - p_i\|_2)$. Then, modulate the performance by the importance $\phi(q)$ of the location q . Finally, the infinitesimal sum of this quantity over the environment S gives rise to $\mathcal{H}(p_1, \dots, p_n)$ as a measure of the overall coverage provided by $p_1, \dots, p_n$.

From here, we can formulate the following geometric optimization problem, known as the *continuous p-median problem*, see Drezner (1995):

$$\max_{\{p_1, \dots, p_n\} \subset S} \mathcal{H}(p_1, \dots, p_n). \quad (2)$$

The expected-value multicenter function can be alternatively described in terms of the Voronoi partition of S generated by $P = \{p_1, \dots, p_n\}$. Let us define the set

$$\mathcal{C} = \{(p_1, \dots, p_n) \in (\mathbb{R}^m)^n \mid p_i = p_j \text{ for some } i \neq j\},$$

consisting of tuples of n points, where some of them are repeated. Then, for $(p_1, \dots, p_n) \in S^n \setminus \mathcal{C}$, one has

$$\mathcal{H}(p_1, \dots, p_n) = \sum_{i=1}^n \int_{V_i(P)} f(\|q - p_i\|_2) \phi(q) dq. \quad (3)$$

This expression of $\mathcal{H}$ is appealing because it clearly shows the result of the overall coverage of the environment as the aggregate contribution of all individual nodes. If $(p_1, \dots, p_n) \in \mathcal{C}$, then a similar decomposition of $\mathcal{H}$ can be written in terms of the distinct points $P = \{p_1, \dots, p_n\}$.

Inspired by (3), a more general version of the expected-value multicenter function is given next. Given $(p_1, \dots, p_n) \in S^n$ and a partition $\{W_1, \dots, W_n\}$ of S , let

$$\mathcal{H}(p_1, \dots, p_n, W_1, \dots, W_n) = \sum_{i=1}^n \int_{W_i} f(\|q - p_i\|_2) \phi(q) dq. \quad (4)$$

For all $(p_1, \dots, p_n) \in S^n \setminus \mathcal{C}$, we have that $\mathcal{H}(p_1, \dots, p_n) = \mathcal{H}(p_1, \dots, p_n, V_1(P), \dots, V_n(P))$. With respect to, e.g., sensor networks, this function evaluates the performance associated with an assignment of the sensors' locations at $(p_1, \dots, p_n)$ and a region assignment $(W_1, \dots, W_n)$.

Moreover, one can establish that the Voronoi partition (Du et al. 1999) $\mathcal{V}(P)$ is optimal for $\mathcal{H}$ among all partitions of S . That is, let $P = \{p_1, \dots, p_n\} \in S$. For any performance function f and for any partition $\{W_1, \dots, W_n\}$ of S ,

$$\mathcal{H}(p_1, \dots, p_n, V_1(P), \dots, V_n(P)) \geq$$

$$\mathcal{H}(p_1, \dots, p_n, W_1, \dots, W_n),$$

with a strict inequality if any set in $\{W_1, \dots, W_n\}$ differs from the corresponding set in $\{V_1(P), \dots, V_n(P)\}$ by a set of positive measure.

Next, we characterize the smoothness of the expected-value multicenter function (Cortés et al. 2005). Before stating the precise properties, let us introduce some useful notation. For a performance function f , let $\text{discont}(f)$ denote the (finite) set of points where f is discontinuous. For each $a \in \text{discont}(f)$, define the limiting values from the left and from the right, respectively, as

$$f_-(a) = \lim_{x \rightarrow a^-} f(x), \quad f_+(a) = \lim_{x \rightarrow a^+} f(x).$$

Recall that the line integral of a function $g : \mathbb{R}^2 \rightarrow \mathbb{R}$ over a curve C parameterized by a continuous and piecewise continuously differentiable map $\gamma : [0, 1] \rightarrow \mathbb{R}^2$ is defined as follows:

$$\int_C g = \int_C g(\gamma) d\gamma := \int_0^1 g(\gamma(t)) \|\dot{\gamma}(t)\|_2 dt,$$

and is independent of the selected parameterization.

Now, given a set $S \subset \mathbb{R}^m$ that is bounded and measurable, a density $\phi : S \rightarrow \mathbb{R}_{\geq 0}$, and a performance function $f : \mathbb{R} \rightarrow_{\geq 0} \mathbb{R}$, the expected-value multicenter function $\mathcal{H} : S^n \rightarrow \mathbb{R}$ is globally Lipschitz (Given $S \subset \mathbb{R}^h$, a function $f : S \rightarrow \mathbb{R}^k$ is globally Lipschitz if there exists $K \in \mathbb{R}_{>0}$ such that $\|f(x) - f(y)\|_2 \leq K\|x - y\|_2$ for all $x, y \in S$). on S^n ; and continuously differentiable on $S^n \setminus \mathcal{C}$, where for $i \in \{1, \dots, n\}$

$$\begin{aligned} \frac{\partial \mathcal{H}}{\partial p_i}(P) &= \int_{V_i(P)} \frac{\partial}{\partial p_i} f(\|q - p_i\|_2) \phi(q) dq \\ &+ \sum_{a \in \text{discont}(f)} (f_-(a) - f_+(a)) \\ &\int_{V_i(P) \cap \partial \bar{B}(p_i, a)} n_{\text{out}}(q) \phi(q) dq, \end{aligned} \quad (5)$$

where n_{out} is the outward normal vector to $\bar{B}(p_i, a)$.

Different performance functions lead to different expected-value multicenter functions. Let us examine some important cases.

Distortion Problem

Consider the performance function $f(x) = -x^2$. Then, on $S^n \setminus \mathcal{C}$, the expected-value multicenter function takes the form

$$\mathcal{H}_{\text{distor}}(p_1, \dots, p_n) = - \sum_{i=1}^n \int_{V_i(P)} \|q - p_i\|_2^2 \phi(q) dq.$$

In signal compression $-\mathcal{H}_{\text{distor}}$ is referred to as the *distortion function* and is relevant in many disciplines where including vector quantization, signal compression, and numerical integration; see Gray and Neuhoff (1998) and Du et al. (1999). Here, distortion refers to the average deformation (weighted by the density ϕ) caused by reproducing $q \in S$ with the location p_i in $P = \{p_1, \dots, p_n\}$ such that $q \in V_i(P)$. By means of the Parallel Axis Theorem (see Hibbeler 2006), it is possible to express $\mathcal{H}_{\text{distor}}$ as a sum

$$\begin{aligned} \mathcal{H}_{\text{distor}}(p_1, \dots, p_n, W_1, \dots, W_n) \\ = \sum_{i=1}^n -J_\phi(W_i, CM_\phi(W_i)) \\ - A_\phi(W_i) \|p_i - CM_\phi(W_i)\|_2^2, \quad (6) \end{aligned}$$

where $J_\phi(W, p) = \int_W \|q - p\|^2 \phi(q) dq$ is the so-called moment of inertia of the region W about p with respect to ϕ . In this way, the terms $J_\phi(W_i, CM_\phi(W_i))$ only depend on the partition of S , whereas the second terms multiplied by $A_\phi(W_i)$ include the particular location of the points. As a consequence of this observation, the optimality of the centroid locations for $\mathcal{H}_{\text{distor}}$ follows Bullo et al. (2009). More precisely, let $\{W_1, \dots, W_n\}$ be a partition of S . Then, for any set points $P = \{p_1, \dots, p_n\}$ in S ,

$$\begin{aligned} \mathcal{H}_{\text{distor}}(CM_\phi(W_1), \dots, CM_\phi(W_n), W_1, \dots, W_n) \\ \geq \mathcal{H}_{\text{distor}}(p_1, \dots, p_n, W_1, \dots, W_n), \end{aligned}$$

and the inequality is strict if there exists $i \in \{1, \dots, n\}$ for which W_i has nonvanishing area and $p_i \neq CM_\phi(W_i)$. In other words, the centroid locations $CM_\phi(W_1), \dots, CM_\phi(W_n)$ are optimal for $\mathcal{H}_{\text{distor}}$ among all configurations in S .

Note that when $n = 1$, the node location that optimizes $p \mapsto \mathcal{H}_{\text{distor}}(p)$ is the centroid of the set S , denoted by $CM_\phi(S)$.

Recall that the gradient of $\mathcal{H}_{\text{distor}}$ on $S^n \setminus \mathcal{C}$ takes the form,

$$\begin{aligned} \frac{\partial \mathcal{H}_{\text{distor}}}{\partial p_i}(P) = 2A_\phi(V_i(P))(CM_\phi(V_i(P)) - p_i), \\ i \in \{1, \dots, n\}, \end{aligned}$$

that is, the i th component of the gradient points in the direction of the vector going from p_i to the centroid of its Voronoi cell. The critical points of $\mathcal{H}_{\text{distor}}$ are therefore the set of centroidal Voronoi configurations in S . This is a natural generalization of the result for the case $n = 1$, where the optimal node location is the centroid $CM_\phi(S)$.

Area Problem

For $r \in \mathbb{R}_{>0}$, consider the performance function $f(x) = 1_{[0,r]}(x)$, that is, the indicator function of the closed interval $[0, r]$. Then, the expected-value multicenter function becomes

$$\begin{aligned} \mathcal{H}_{\text{area},r}(p_1, \dots, p_n) = \sum_{i=1}^n A_\phi(V_i(P) \cap \overline{B}(p_i, r)) \\ = A_\phi(\cup_{i=1}^n \overline{B}(p_i, r)), \end{aligned}$$

which corresponds to the area, measured according to ϕ , covered by the union of the n balls $\overline{B}(p_1, r), \dots, \overline{B}(p_n, r)$.

Let us see how the computation of the partial derivatives of $\mathcal{H}_{\text{area},r}$ specializes in this case. Here, the performance function is differentiable everywhere except at a single discontinuity, and its derivative is identically zero. Therefore, the first term in (5) vanishes. The gradient of $\mathcal{H}_{\text{area},r}$ on $S^n \setminus \mathcal{C}$ then takes the form, for each $i \in \{1, \dots, n\}$,

$$\frac{\partial \mathcal{H}_{\text{area},r}}{\partial p_i}(P) = \int_{V_i(P) \cap \partial \bar{B}(p_i,r)} \mathbf{n}_{\text{out}}(q) \phi(q) dq,$$

where $\mathbf{n}_{\text{out}}$ is the outward normal vector to $\bar{B}(p_i, r)$. The critical points of $\mathcal{H}_{\text{area},r}$ correspond to configurations with the property that each p_i is a local maximum for the area of $V_{i,r}(P) = V_i(P) \cap \bar{B}(p_i, r)$ at fixed $V_i(P)$. We refer to these configurations as *r-limited area-centered Voronoi configurations*.

Optimal Deployment Algorithms

Once a set of optimal deployment configurations have been characterized, the next step is to devise a distributed algorithm that allows a group of mobile robots to converge to such configurations. Gradient algorithms are the first of the options that should be explored.

For the expected-value multicenter functions, robots whose dynamics can be described by first-order integrator dynamics and which can communicate at predetermined *communication rounds* of a fixed time schedule, these laws present a similar structure, loosely described as follows:

[*Informal description*] In each communication round, each robot performs the following tasks: (i) it transmits its position and receives its neighbors' positions; (ii) it computes a notion of the geometric center of its own cell, determined according to some notion of partition of the environment. (iii) Between communication rounds, each robot moves toward this center.

The notions of geometric center and of partition of the environment differ depending on what is the type of expected-value multicenter function used. In the *Voronoi-center deployment algorithm*, the geometric center just reduces to $CM_\phi(V_i)$. In the *limited-Voronoi-normal* deployment problem in (ii), each agent computes the direction of $v = \frac{\partial \mathcal{H}_{\text{area},r}}{\partial p_i}$ for some r and (iii) moves for a maximum step size in this direction to ensure the area function will be decreased.

The Voronoi-center deployment algorithm achieves convergence of a set of nodes to a

centroidal Voronoi configuration, thus maximizing the expected-value multicenter function $\mathcal{H}_{\text{distor}}$. The algorithm is distributed over the proximity graph $\mathcal{G}_D$, as the computation of the centroids requires information in $\mathcal{N}_{\mathcal{G}_D}(p_i)$, for each $i \in \{1, \dots, n\}$. Additional properties of this algorithm are that the algorithm is adaptive to agent departures or arrivals and amenable to asynchronous implementations.

On the other hand, the limited-Voronoi-normal deployment algorithm achieves convergence to a set that locally maximizes the area covered by the set of sensing balls. The algorithm is distributed in the sense that agents only need to know information from neighbors in the proximity graph $\mathcal{G}_{2r}$ or, more precisely, $\mathcal{G}_{LD,r}$. Thus, it can be implemented by agents that employ range-limited interactions. It enjoys similar robustness properties as the Voronoi-center deployment algorithm.

Simulation Results

We show evolutions of the Voronoi-centroid deployment algorithm in Fig. 1. One can verify that the final network configuration is a centroidal Voronoi configuration. For each evolution we depict the initial positions, the trajectories, and the final positions of all robots.

Finally, we show an evolution of limited-Voronoi-normal deployment algorithm in Fig. 2. One can verify that the final network configuration is an $\frac{r}{2}$ -limited area-centered Voronoi configuration. In other words, the deployment task is achieved.

Future Directions for Research

The algorithms described above achieve locally optimal deployment configurations with respect to expected-value multicenter functions. However, this simplified setting does not account for many important constraints, such as obstacles and deployment in non-convex environments (Pimenta et al. 2008; Caicedo-Núñez and Žefran 2008), deployment with visibility sensors, range-limited and wedge-shaped footprints (Ganguli et al. 2006; Laventall

and Cortés 2009), and energy and vehicle dynamical restrictions (Kwok and Martínez 2010a, b). Deployment strategies find application in exploration and data gathering tasks, and so these algorithms have been expanded to account for uncertainty and learning of unknown density functions (Schwager et al. 2009; Graham and Cortés 2012; Zhong and Cassandras 2011; Martínez 2010). Gossip and self-triggered communications (Bullo et al. 2012; Nowzari and Cortés 2012), self-triggered computations for region approximation (Ru and Martínez 2013), and area equitable partitions (Cortés 2010) have also been investigated. Much work is currently being devoted to solve on the current limitations of these nontrivial extensions, which make the problem settings significantly harder to solve.

Optimal Sampled-Data Control

Yutaka Yamamoto

Graduate School of Informatics, Kyoto University, Kyoto, Japan

Abstract

This entry gives a brief overview on the modern development of sampled-data control. Sampled-data systems intrinsically involve a mixture of two different time sets, one continuous and the other discrete. Due to this, sampled-data systems cannot be characterized in terms of the standard notions of transfer functions, steady-state response, or frequency response. The technique of lifting resolves this difficulty and enables the recovery of such concepts and simplified solutions to sampled-data H^∞ and H^2 optimization problems. We review the lifting point of view and its application to such optimization problems and finally present an instructive numerical example.

Keywords

Computer control · Frequency response · H^∞ and H^2 optimization · Lifting · Transfer operator

Introduction

A sampled-data control system consists of a continuous-time plant and a discrete-time controller, with sample and hold devices that serve as an interface between these two components. As can be seen from this fact, sampled-data systems are *not* time-invariant, and various problems arise from this property.

To be more specific, consider the unity-feedback control system shown in Fig. 1; r is the reference signal, y the system output, and e the error signal. These are continuous-time signals. The error $e(t)$ goes through the *sampler*

Optimal Sampled-Data Control, Fig. 1 A unity-feedback system

Optimal Sampled-Data Control, Fig. 2 Sampling with 0-order hold

(or an *A/D converter*) $\mathcal{S}$. This sampler reads out the values of $e(t)$ at every time step h called the *sampling period* and produces a discrete-time signal $e_d[k]$, $k = 0, 1, 2, \dots$ (see Fig. 2). In particular, the sampling operator $\mathcal{S}$ acts on a continuous-time signal $w(t)$, $t \geq 0$, as

$$\mathcal{S}(w)[k] := w(kh), \quad k = 0, 1, 2, \dots$$

The discretized signal is then processed by the discrete-time controller $C(z)$ and becomes a control input u_d . There can also be a quantization effect, although for the sake of simplicity, it is neglected here. The obtained signal u_d then goes through another interface $\mathcal{H}$ called a *hold device* or a *D/A converter* to become a continuous-time signal. A typical example is the *0-order hold* where $\mathcal{H}$ simply maintains the value of a discrete-time signal $w[k]$ constant as its output until the next sampling time:

$$(\mathcal{H}(w[k]))(t) := w[k], \quad \text{for } kh \leq t < (k+1)h.$$

A typical sample-and-hold action is shown in Fig. 2.

While one can consider a nonlinear plant P or controller C , or infinite-dimensional P and C , we confine ourselves to linear and finite-dimensional P and C and also suppose that P and C are time-invariant in continuous-time and in discrete-time, respectively.

The Main Difficulty

As stated above, the unity-feedback system Fig. 1 is not time-invariant either in continuous-time or in discrete-time, even when the plant and controller are both time-invariant in their respective domains of operators. The mixture of the two time sets prohibits the total closed-loop system from being time-invariant.

The lack of time-invariance implies that we cannot naturally associate to sampled-data systems such classical concepts of transfer functions, steady-state response and frequency response.

One can regard Fig. 1 as a time-invariant discrete-time system by ignoring the intersample behavior and focusing attention on the sample-point behavior only. But the obtained model does not then reflect what happens between sampling times. This approach can lead to the neglect of undesirable intersample oscillations, called *ripples*. To monitor the intersample behavior, the notion of the *modified z-transform* was introduced; see, e.g., Jury (1958) and Ragazzini and Franklin (1958); however, this transform is usable only *after the controller has been designed* and hence not for the design problems considered in this entry.

Lifting: A Modern Approach

A new approach was introduced around 1990–1991 (Bamieh et al. 1991; Tadmor 1991; Toivonen 1992; Yamamoto 1990, 1994). The new idea, now called *lifting*, makes it possible to describe sampled-data systems via a *time-invariant model while maintaining the intersample behavior*.

Let $f(t)$ be a continuous-time signal. Instead of sampling $f(t)$, we will represent it as a *sequence of functions*. Namely, we set up the correspondence (see Fig. 3):

$$\begin{aligned} \mathcal{L} : f &\mapsto \{f[k](\theta)\}_{k=0}^{\infty}, \\ f[k](\theta) &= f(kh + \theta), \quad 0 \leq \theta < h. \end{aligned} \quad (1)$$

This idea makes it possible to view a (time-invariant or even periodically time-varying) *continuous-time* system as a linear, *time-invariant discrete-time* system. Let

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t). \end{aligned} \quad (2)$$

be a given continuous-time plant and lift the input $u(t)$ to obtain $u[k](\cdot)$. We apply this lifted input with the timing $t = kh$ (h is the prespecified sampling rate as above) and observe how it affects the system. Let $x[k]$ be the state at time $t = kh$. The state $x[k+1]$ at time $(k+1)h$ is given by

$$x[k+1] = e^{Ah}x[k] + \int_0^h e^{A(h-\tau)}Bu[k](\tau)d\tau. \quad (3)$$

The right-hand side integral defines an operator $L^2[0, h] \rightarrow \mathbb{R}^n : u(\cdot) \mapsto \int_0^h e^{A(h-\tau)}Bu(\tau)d\tau$. While the state-transition (3) only describes a discrete-time update, the system keeps producing an output during the intersample period. If we consider the lifting of $x(t)$, it is seen to be described by

$$x[k](\theta) = e^{A\theta}x[k] + \int_0^\theta e^{A(\theta-\tau)}Bu[k](\tau)d\tau.$$

As such, the lifted output $y[k](\cdot)$ is given by

$$\begin{aligned} y[k](\theta) &= Ce^{A\theta}x[k] \\ &\quad + \int_0^\theta Ce^{A(\theta-\tau)}Bu[k](\tau)d\tau. \end{aligned} \quad (4)$$

Observe that formulas (3) and (4) take the form

$$\begin{aligned} x[k+1] &= \mathcal{A}x[k] + \mathcal{B}u[k] \\ y[k] &= \mathcal{C}x[k] + \mathcal{D}u[k], \end{aligned}$$

and the operators $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ do not depend on the time variable k . In other words, it is possible to describe this continuous-time system with discrete timing, once we adopt the lifting point of view. To be more precise, the operators $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ are defined as follows:

$$\begin{aligned} \mathcal{A} : \mathbb{R}^n &\rightarrow \mathbb{R}^n : x \mapsto e^{Ah}x \\ \mathcal{B} : L^2[0, h] &\rightarrow \mathbb{R}^n : u \mapsto \int_0^h e^{A(h-\tau)}Bu(\tau)d\tau \\ \mathcal{C} : \mathbb{R}^n &\rightarrow L^2[0, h] : x \mapsto Ce^{A(\cdot)}x \\ \mathcal{D} : L^2[0, h] &\rightarrow L^2[0, h] : u \\ &\mapsto \int_0^\cdot Ce^{A(\cdot-\tau)}Bu(\tau)d\tau \end{aligned} \quad (5)$$

Thus the continuous-time plant (2) can be described by a *time-invariant* discrete-time model. Once this is done, it is straightforward to connect this expression with a discrete-time controller, and hence, sampled-data systems (for example, Fig. 1) can be fully described by time-invariant discrete-time equations, without

Optimal Sampled-Data Control, Fig. 3 Lifting

discarding the intersampling information. We will also denote the overall equation (with discrete-time controller included) abstractly in the form

$$\begin{aligned} x[k+1] &= \mathcal{A}x[k] + \mathcal{B}u[k] \\ y[k] &= \mathcal{C}x[k] + \mathcal{D}u[k]. \end{aligned} \quad (6)$$

While the obtained discrete-time model is a time-invariant, the input and output spaces are now infinite dimensional. Its *transfer function (operator)* is defined as

$$G(z) := \mathcal{D} + \mathcal{C}(zI - \mathcal{A})^{-1}\mathcal{B}. \quad (7)$$

Note that $\mathcal{A}$ in (6) is a matrix because it is so for $\mathcal{A}$ in (5). Hence, (6) is stable if $G(z)$ is analytic for $\{z : |z| \geq 1\}$, provided that there is no unstable pole-zero cancellation.

Definition 1 Let $G(z)$ be the transfer operator of the lifted system given by (7), which is stable in the sense above. The *frequency response operator* is the operator

$$G(e^{j\omega h}) : L^2[0, h] \rightarrow L^2[0, h] \quad (8)$$

regarded as a function of $\omega \in [0, \omega_s)$ ($\omega_s := 2\pi/h$). Its *gain* at ω is defined to be

$$\|G(e^{j\omega h})\| = \sup_{v \in L^2[0, h]} \frac{\|G(e^{j\omega h})v\|}{\|v\|}. \quad (9)$$

The maximum $\|G(e^{j\omega h})\|$ over $[0, \omega_s)$ is the H^∞ norm of $G(z)$. The H^2 -norm of G is defined by

$$\begin{aligned} \|G\|_2 : \\ = \left(\frac{h}{2\pi} \int_0^{2\pi/h} \text{trace} \{G^*(e^{j\omega h})G(e^{j\omega h})\} d\omega \right)^{1/2}, \end{aligned} \quad (10)$$

where the *trace* here is taken in the sense of the Hilbert-Schmidt norm; see Chen and Francis (1995) for details.

H^∞ and H^2 Control Problems

A significant consequence of the lifting approach described above is that various robust control problems such as H^∞ and H^2 control problems for sampled-data control systems can be converted to corresponding discrete-time (finite-dimensional) problems. The approach was initiated by Chen and Francis (1990) and later solved by Bamieh and Pearson (1992), Kabamba and Hara (1993), Sivashankar and Khargonekar (1994), Tadmor (1991), and Toivonen (1992) in more complete forms; see Chen and Francis (1995) for the pertinent historical accounts.

Let us introduce the notion of generalized plants. Suppose that a continuous-time plant is given in the following model:

$$\begin{aligned} \dot{x}_c(t) &= Ax_c(t) + B_1w(t) + B_2u(t) \\ z(t) &= C_1x_c(t) + D_{11}w(t) + D_{12}u(t) \\ y(t) &= C_2x_c(t) \end{aligned} \quad (11)$$

Here w is the exogenous input, $u(t)$ control input, $y(t)$ measured output, and $z(t)$ is the controlled output. The objective is to design a controller that takes the sampled measurements of y and returns a control variable u according to the following formulas:

$$\begin{aligned} x_d[k+1] &= A_dx_d[k] + B_dSy[k] \\ v[k] &= C_dx_d[k] + D_dSy[k] \\ u[k](\theta) &= H(\theta)v[k] \end{aligned} \quad (12)$$

Optimal Sampled-Data Control, Fig. 4 Sampled feedback system

where $H(\theta)$ is a suitable hold function. This is depicted in Fig. 4. The objective here is to design or characterize a controller that achieves a prescribed performance level $\gamma > 0$ in such a way that

$$\|T_{zw}\|_\infty < \gamma \quad (13)$$

where T_{zw} denotes the closed-loop transfer operator from w to z . This is the H^∞ control problem for sampled-data systems. If we take the H^2 -norm (10) instead, then the problem becomes that of the H^2 (sub)optimal control problem.

The difficulty here is that both w and z are continuous-time variables, and hence their lifted variables are infinite dimensional. A remarkable fact here is that the H^∞ problem (and the H^2 problem as well) (13) can be equivalently transformed to an H^∞ problem for a *finite-dimensional* discrete-time system. We will indicate in the next section how this can be done.

H^∞ Norm Computation and Reduction to Finite Dimension

Let us write the system (11) and (12) in the form

$$\begin{aligned} x[k+1] &= Ax[k] + Bu[k] \\ y[k] &= Cx[k] + Du[k]. \end{aligned} \quad (14)$$

as in (6). For simplicity of treatments, assume D_{11} in (11) to be zero; for the general case, see Yamamoto and Khargonekar (1996).

Let $G(z)$ be the transfer operator $G(z) := \mathcal{D} + \mathcal{C}(zI - \mathcal{A})^{-1}\mathcal{B}$. The H^∞ norm of G is given as the maximum of the singular values of the gain $G(e^{j\omega h})$ for $\omega \in [0, 2\pi/h]$.

Now consider the singular value equation

$$(\gamma^2 I - G^* G(e^{j\omega h}))w = 0. \quad (15)$$

and suppose that $\gamma > \|\mathcal{D}\|$. A crux here is that $\mathcal{A}, \mathcal{B}, \mathcal{C}$ are finite-rank operators, and we can reduce this to a finite-dimensional rank condition. Taking the adjoint of (14), we obtain

$$p[k] = \mathcal{A}^* p_{k+1} + \mathcal{C}^* v[k]$$

$$e[k] = \mathcal{B}^* p_{k+1} + \mathcal{D}^* v[k].$$

Taking the z -transforms of both sides, setting $z = e^{j\omega h}$, and substituting $v = y$ and $e = \gamma^2 w$, we obtain

$$e^{j\omega h} x = \mathcal{A}x + \mathcal{B}w$$

$$p = e^{j\omega h} \mathcal{A}^* p + \mathcal{C}^* (\mathcal{C}x + \mathcal{D}w)$$

$$(\gamma^2 - \mathcal{D}^* \mathcal{D})w = e^{j\omega h} \mathcal{B}^* p + \mathcal{D}^* \mathcal{C}x.$$

Eliminating the variable w then yields

$$\begin{aligned} & \left(e^{j\omega h} \begin{bmatrix} I & \mathcal{B}R_\gamma^{-1}\mathcal{B}^* \\ 0 & \mathcal{A}^* + \mathcal{C}^* \mathcal{D}R_\gamma^{-1}\mathcal{B}^* \end{bmatrix} \right. \\ & \quad \left. - \begin{bmatrix} \mathcal{A} + \mathcal{B}R_\gamma^{-1}\mathcal{D}^* \mathcal{C} & 0 \\ \mathcal{C}^* (I + \mathcal{D}R_\gamma^{-1}\mathcal{D}^*) \mathcal{C} & I \end{bmatrix} \right) \begin{bmatrix} x \\ p \end{bmatrix} = 0 \end{aligned} \quad (16)$$

where $R_\gamma = (\gamma I - \mathcal{D}^* \mathcal{D})$. The important point to be noted here is that all the operators appearing here are actually matrices. For example, $\mathcal{B}$ is an operator from $L^2[0, h]$ to $\mathbb{R}^n$, and its adjoint $\mathcal{B}^*$ is an operator from $\mathbb{R}^n$ to $L^2[0, h]$. Hence, the composition $\mathcal{B}R_\gamma^{-1}\mathcal{B}^*$ is a linear operator from $\mathbb{R}^n$ into itself, i.e., a matrix. Thus, for a given γ , the singular value equation admits a nontrivial

solution w for (15) if and only if the *finite-dimensional equation* (16) admits a nontrivial solution $[x \ p]^T$ (Yamamoto 1993; Yamamoto and Khargonekar 1996). (Note that R_γ is invertible since $\gamma > \|\mathcal{D}\|$.)

It is possible to find matrices $\bar{A}$, $\bar{B}$, $\bar{C}$ such that $\bar{A} = \mathcal{A} + \mathcal{B}R_\gamma^{-1}\mathcal{D}^*\mathcal{C}$, $\bar{B}\bar{B}^*/\gamma^2 = \mathcal{B}R_\gamma^{-1}\mathcal{B}^*$, and $\bar{C}^*\bar{C} = \mathcal{C}^*(I + \mathcal{D}R_\gamma^{-1}\mathcal{D}^*)\mathcal{C}$, and hence (16) is equivalent to

$$\left(\lambda \begin{bmatrix} I & -\bar{B}\bar{B}^*/\gamma^2 \\ 0 & \bar{A}^* \end{bmatrix} - \begin{bmatrix} \bar{A} & 0 \\ -\bar{C}^*\bar{C} & I \end{bmatrix} \right) \begin{bmatrix} x \\ p \end{bmatrix} = 0 \quad (17)$$

for $\lambda = e^{j\omega h}$. In other words, we have that $\|G\|_\infty < \gamma$ if and only if there exists no λ of modulus 1 such that (17) holds.

It can be proven that by substituting the expressions of (11) and (12) for $(\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D})$, one obtains a finite-dimensional discrete-time generalized plant G_d with digital controller (12) such that $\|G\|_\infty < \gamma$ if and only if $\|G_d\|_\infty < \gamma$. The precise formulas for the discrete-time plant can be found, e.g., Bamieh and Pearson (1992), Chen and Francis (1995), Kabamba and Hara (1993), Yamamoto and Khargonekar (1996), and Cantoni and Glover (1997).

An H^∞ Design Example

For sampled-data control systems, there used to be, and still is, a rather common myth that if one takes a sufficiently fast sampling rate, it will not cause a major problem. This can be true for continuous-time design, but we here show that if we employ a sample-point discretization without a performance consideration for intersampling behavior, fast sampling rates can cause a serious problem.

Take a simple second-order plant $P(s) = 1/(s^2 + 0.1s + 1)$ and consider the disturbance rejection problem minimizing the H^∞ -norm from w to z as given in Fig. 5. Set the sampling time $h = 0.5$. We execute the following:

- Sampled-data H^∞ design with the generalized plant

$$G(s) = \begin{bmatrix} P(s) & P(s) \\ P(s) & P(s) \end{bmatrix},$$

- Discrete-time H^∞ design with the discrete-time generalized plant $G_d(z)$ given by the step-invariant transformation (see, e.g., Chen and Francis 1995) of $G(s)$.

Figures 6 and 7 show the frequency and time responses of the two resulting closed-loop systems, respectively. In Fig. 6, the solid curve shows the response of the sampled design, while the dash-dotted curve shows the discrete-time frequency response, but purely reflecting its sample-point behavior only. At first glance, it may appear that the discrete-time design performs better. But when we actually compute the lifted sampled-data frequency response in the sense defined in Definition 1, it becomes obvious that the sampled-data design is far superior. The dashed curve shows the frequency response of the closed-loop, i.e., that of $G(s)$ connected with the discrete-time designed K_d . The response is similar to the discrete-time frequency response in low frequency but exhibits a very sharp peak around the Nyquist frequency (i.e., half the sampling frequency; in the present case, $\pi/h \sim 6.28$ rad/s, i.e., $1/2h = 1$ Hz).

This can also be verified from the initial-state responses Fig. 7 with $x(0) = (1, 1)$. The solid curve shows the sampled-data design and the dashed curve the discrete-time one. Both responses decay to zero rapidly *at sampled instants* as shown by the circles for the discrete-time design. But the discrete-time design exhibits very large ripples, with period approximately 1 s. This corresponds to 1 Hz, which is the same as $2\pi = \pi/h$ [rad/s], i.e., the Nyquist frequency. This is precisely captured in the lifted frequency response in Fig. 6.

It is worth noting that when we take the sampling period h smaller, the response for the discrete-time design becomes even more oscillatory and shows a very high peak in the frequency response.

Summary, Bibliographical Notes, and Future Directions

We have given a short summary of the main achievements of modern sampled-data control theory. Particularly, we have reviewed how the technique of lifting resolved the intrinsic difficulty arising from the mixture of two distinct time sets: continuous and discrete. This idea further led to the new notions of transfer operators and frequency response. These notions together enabled us to treat optimal sampled-data control problems in a unified and transparent way. We have outlined how the sampled-data H^∞ control problem can equivalently be reduced to a corresponding discrete-time H^∞ problem, without sacrificing the performance in the intersample behavior. This has been exemplified by a numerical example.

For classical treatments of sampled-data control, it is instructive to consult Jury (1958) and Ragazzini and Franklin (1958). The textbook Åström and Wittenmark (1996) covers both classical and modern aspects of digital control. For a mathematical background of the computation of adjoints treated in section “ H^∞ Norm Computation and Reduction to Finite Dimension,” consult Yamamoto (2012) as well as Yamamoto (1993).

There are other performance indices for optimality, typically those arising from H^2 and L^1 norms. These problems have also been studied extensively, and fairly complete solutions are available. For the lack of space, we cannot list all references, and the reader is referred to Chen and Francis (1995) and Yamamoto (1999), Yamamoto and Nagahara (2017) for a more concrete survey and references therein.

Optimal Sampled-Data Control, Fig. 7

Initial-state responses
 $h = 0.5$

For actual computation of these optimal control problems, we often resort to the so-called fast-sample/fast-hold approximation. For this technique, consult Anderson and Keller (1998), and also Yamamoto et al. (1999, 2002). The latter two discuss convergence properties of such approximations. Recently Hagiwara and coworkers (Hagiwara and Umeda 2008; Kim and Hagiwara 2016) introduced a modified version of fast-sample/fast-hold approximation by combining them with lifting.

It is also known that sampled-data systems exhibit some odd unstable zeros when sampled and combined with a (zero-order) hold (Åström et al. 1984). Much research has been conducted to circumvent this effect via multirate techniques, e.g., Mita et al. (1990). It has been also shown that such zeros disappear if one considers a lifted sampled-data model of the continuous-time system (Yamamoto et al. 2017a).

Until quite recently, the Nyquist frequency was regarded to be the upper bound for control, based on the sampling theorem. On the other hand, there are varied situations in which one needs to track or reject those signals beyond the Nyquist frequency. Control of hard-disc drives

where one needs to reject disturbance beyond the Nyquist frequency is such an example (Atsumi 2010). Some efforts have been made recently by utilizing a proper signal model and a multirate techniques (Yamamoto et al. 2016, 2017b; Zheng et al. 2016). See also Nagahara and Yamamoto (2016) for an application to repetitive control systems.

For nonlinear systems, the situation is quite different. At the moment, there does not seem to be a model similar to the lifted model discussed here. See, e.g., Nesić and Teel (2007), Monaco and Normand-Cyrot (1995), and Yuz and Goodwin (2005).

Sampled-data control has much to do with signal processing. Indeed, since it can optimize continuous-time performance, it can shed new light on digital signal processing. Traditionally, Shannon's paradigm is based on the perfect band-limiting hypothesis, and the sampling theorem has been prevalent in the signal processing community. Since the sampling theorem opts for perfect reconstruction, the resulting theory reduces mostly to discrete-time problems. In other words, the intersample information is buried in the sampling theorem. It should,

however, be noted that the very stringent band-limiting hypothesis is almost never satisfied in reality, and various approximations are necessitated. In contrast, sampled-data control can provide an optimal platform for dealing with and optimizing the response between sampling points when the band-limiting hypothesis does not hold. See, for example, Yamamoto et al. (2012) and Nagahara and Yamamoto (2012) for the idea and some efforts in this direction.

Abstract

This entry reviews optimization algorithms for both linear and nonlinear model predictive control (MPC). Linear MPC typically leads to specially structured convex quadratic programs (QP) that can be solved by structure exploiting active set, interior point, or gradient methods. Nonlinear MPC leads to specially structured nonlinear programs (NLP)

that can be solved by sequential quadratic programming (SQP) or nonlinear interior point methods.

Keywords

Banded matrix factorization · Convex optimization · Karush-Kuhn-Tucker (KKT) conditions · Sparsity exploitation

Introduction

Model predictive control (MPC) needs to solve at each sampling instant an optimal control problem with the current system state $\bar{x}_0$ as initial value. MPC optimization is almost exclusively based on the so-called *direct approach* which first discretizes the continuous time system to obtain a discrete time optimal control problem (OCP). This OCP has as optimization variables a state trajectory $X = [x_0^\top, \dots, x_N^\top]^\top$ with $x_i \in \mathbb{R}^{n_x}$ for $i = 0, \dots, N$ and a control trajectory $U = [u_0^\top, \dots, u_{N-1}^\top]^\top$ with $u_i \in \mathbb{R}^{n_u}$ for $i = 0, \dots, N - 1$. For simplicity of presentation, we restrict ourselves to the time-independent case, and the OCP we treat in this article is stated as follows:

$$\underset{X, U}{\text{minimize}} \quad \sum_{i=0}^{N-1} L(x_i, u_i) + E(x_N) \quad (1a)$$

$$\text{subject to} \quad x_0 - \bar{x}_0 = 0, \quad (1b)$$

$$x_{i+1} - f(x_i, u_i) = 0, \quad i = 0, \dots, N - 1, \quad (1c)$$

$$h(x_i, u_i) \leq 0, \quad i = 0, \dots, N - 1, \quad (1d)$$

$$r(x_N) \leq 0. \quad (1e)$$

The MPC objective is stated in Eq. (1a), the system dynamics enter via Eq. (1c), while path and terminal constraints enter via Eqs. (1d) and (1e). All functions are assumed to be differentiable and to have appropriate dimensions ($h(x, u) \in \mathbb{R}^{n_h}$ and $r(x) \in \mathbb{R}^{n_r}$). Note that $\bar{x}_0 \in \mathbb{R}^{n_x}$ is not an optimization variable, but a parameter upon

which the OCP depends via the initial value constraint in Eq. (1b). The optimal solution trajectories depend only on this value and can thus be denoted by $X^*(\bar{x}_0)$ and $U^*(\bar{x}_0)$. Obtaining them, in particular the first control value $u_0^*(\bar{x}_0)$, as fast and reliably as possible for each new value of $\bar{x}_0$ is the aim of all MPC optimization algorithms. The most important dividing line is between convex and non-convex optimal control problems (OCP). If the OCP is convex, algorithms exist that find a global solution reliably and in computable time. If the OCP is not convex, one usually needs to be satisfied with approximations of locally optimal solutions. The OCP (1) is convex if the objective (1a) and all components of the inequality constraint functions (1d) and (1e) are convex and if the equality constraints (1c) are linear.

We typically speak of *linear MPC* when the OCP to be solved is convex, and otherwise of *nonlinear MPC*.

General Algorithmic Features for MPC Optimization

In MPC we would dream to have the solution to a new optimal control problem instantly, which is impossible due to computational delays. Several ideas can help us to deal with this issue.

Off-line Precomputations and Code Generation

As consecutive MPC problems are similar and differ only in the value $\bar{x}_0$, many computations can be done once and for all before the MPC controller execution starts. Careful preprocessing and code optimization for the model routines is essential, and many tools automatically generate custom solvers in low-level languages. The generated code has fixed matrix and vector dimensions, has no online memory allocations, and contains a minimal number of if-then-else statements to ensure a smooth computational flow.

Delay Compensation by Prediction

When we know how long our computations for solving an MPC problem will take, it is a good idea *not* to address a problem starting at the current state but to simulate at which state

the system will be when we will have solved the problem. This can be done using the MPC system model and the open-loop control inputs that we will apply in the meantime. This feature is used in many practical MPC schemes with non-negligible computation time.

Division into Preparation and Feedback Phase

A third ingredient of several MPC algorithms is to divide the computations in each sampling time into a preparation phase and a feedback phase. The more CPU intensive *preparation phase* is performed with a predicted state $\bar{x}_0$, before the most current state estimate, say $\bar{x}'_0$, is available. Once $\bar{x}'_0$ is available, the *feedback phase* delivers quickly an *approximate* solution to the optimization problem for $\bar{x}'_0$.

Warmstarting and Shift

An obvious way to transfer solution information from one solved MPC problem to the next one uses the existing optimal solution as an initial guess to start the iterative solution procedure of the next problem. We can either directly use the existing solution without modification for warmstarting or we can first shift it in order to account for the advancement of time, which is particularly advantageous for systems with time-varying dynamics or objectives.

Iterating While the Problem Changes

A last important ingredient of some MPC algorithms is the idea to work on the optimization problem while it changes, i.e., to never iterate the optimization procedure to convergence for an MPC problem getting older and older during the iterations but to rather work with the most current information in each new iteration.

Convex Optimization for Linear MPC

Linear MPC is based on a linear system model of the form $x_{i+1} = Ax_i + Bu_i$ and convex objective and constraint functions in (1a), (1d), and (1e). The most widespread linear MPC setting uses a convex quadratic objective function and affine constraints and solves the following quadratic program (QP):

$$\begin{aligned} \underset{X, U}{\text{minimize}} \quad & \frac{1}{2} \sum_{i=0}^{N-1} \begin{bmatrix} x_i \\ u_i \end{bmatrix}^\top \begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix} \begin{bmatrix} x_i \\ u_i \end{bmatrix} + \frac{1}{2} x_N^\top P x_N \\ & (2a) \end{aligned}$$

$$\text{subject to} \quad x_0 - \bar{x}_0 = 0, \quad (2b)$$

$$x_{i+1} - A x_i - B u_i = 0, i = 0, \dots, N-1, \quad (2c)$$

$$b + C x_i + D u_i \leq 0, i = 0, \dots, N-1, \quad (2d)$$

$$c + F x_N \leq 0. \quad (2e)$$

Here, b, c are vectors and Q, S, R, P, C, D, F matrices, and matrices $\begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix}$ and P are symmetric and positive semi-definite to ensure the QP is convex.

Sparsity Exploitation

The QP (2) has a specific sparsity structure that can be exploited in different ways. One way is to reduce the variable space by a procedure called *condensing* and then to solve a smaller-scale QP instead of (2). Another way is to use a *banded matrix factorization*.

Condensing

The constraints (2b) and (2c) can be used to eliminate the state trajectory X . This yields an equivalent but smaller-scale QP of the following form:

$$\underset{U \in \mathbb{R}^{N n_u}}{\text{minimize}} \quad \frac{1}{2} \begin{bmatrix} U \\ \bar{x}_0 \end{bmatrix}^\top \begin{bmatrix} H & G \\ G^\top & J \end{bmatrix} \begin{bmatrix} U \\ \bar{x}_0 \end{bmatrix} \quad (3a)$$

$$\text{subject to} \quad d + K \bar{x}_0 + M U \leq 0. \quad (3b)$$

The number of inequality constraints is the same as in the original QP (2) and given by $m = N n_h + n_r$. Note that in the simplest case without inequalities ($m = 0$), the solution $U^*(\bar{x}_0)$ of the condensed QP can be obtained by setting the gradient of the objective to zero, i.e., by solving $H U^*(\bar{x}_0) + G \bar{x}_0 = 0$. The factorization of a dense matrix H with dimension $N n_u \times N n_u$ needs $O(N^3 n_u^3)$ arithmetic operations, i.e., the computational cost of condensing-based

algorithms typically grows cubically with the horizon length N .

Banded Matrix Factorization

An alternative way to deal with the sparsity is best sketched at hand of a sparse convex QP (2) without inequality constraints (2d) and (2e). We define the vector of Lagrange multipliers $Y = [y_0^\top, \dots, y_N^\top]^\top$ and the Lagrangian function by

$$\begin{aligned} L(X, U, Y) = & y_0^\top (x_0 - \bar{x}_0) + \frac{1}{2} x_N^\top P x_N \\ & + \frac{1}{2} \sum_{i=0}^{N-1} \begin{bmatrix} x_i \\ u_i \end{bmatrix}^\top \begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix} \begin{bmatrix} x_i \\ u_i \end{bmatrix} + y_{i+1}^\top \\ & (x_{i+1} - A x_i + B u_i). \end{aligned} \quad (4)$$

If we reorder all unknowns that enter the Lagrangian and summarize them in the vector

$$W = [y_0^\top, x_0^\top, u_0^\top, y_1^\top, x_1^\top, u_1^\top, \dots, y_N^\top, x_N^\top]^\top$$

the optimal solution $W^*(\bar{x}_0)$ is uniquely characterized by the first-order optimality condition

$$\nabla_W L(W^*) = 0.$$

Due to the linear quadratic dependence of L on W , this is a block-banded linear equation in the unknown W^* :

$$\begin{bmatrix} 0 & I & & & & & & & \\ I & Q & S & -A^\top & & & & & \\ & S^\top & R & -B^\top & & & & & \\ & -A & -B & 0 & I & & & & \\ & & & I & Q & \cdot & \cdot & & \\ & & & & \cdot & \cdot & \cdot & & \\ & & & & \cdot & \cdot & 0 & I & \\ & & & & & & I & P & \end{bmatrix} W^* = \begin{bmatrix} \bar{x}_0 \\ 0 \\ 0 \\ 0 \\ 0 \\ \cdot \\ \cdot \\ \cdot \\ 0 \end{bmatrix}.$$

Because the above matrix has nonzero elements only on a band of width $2n_x + n_u$ around the diagonal, it can be factorized with a computational cost of order $O(N(2n_x + n_u)^3)$.

Treatment of Inequalities

An important observation is that both the unconstrained QP (2) and the equivalent condensed
